LIST OF CONTRIBUTORS TO VOLUME CXIX.

Those whose names are marked with an asterisk have contributed editorial articles.

Aaron, Charles D., M.D., Detroit, Mich.
Ahlswede, Edward H., M.D., Buffalo, N. Y.
Aikman, John, M.D., Rochester, N. Y.
Alexander, M. E., M.D., Waterbury, Conn.
Allport, Frank, M.D., Chicago.
Arroyo, Carlos F., M.D., Tampa, Fla.
Aulde, John, M.D., Philadelphia, Pa.

*Baar, Gustave, M.D., F.A.C.P., Vienna, Austria.
Baer, Louis, M.D., Philadelphia, Pa.
Baird, John H., M.D., New York.
Baldwin, Jane North, M.D., New York.
*Bancroft, Frederic W., M.D., New York.
Barnes, George Edward, M.D., Herkimer, N. Y.
Barr, Sir James, C.B.E., D.L., LL.D., M.D., F.R.C.P., F.R.S.E., London England.
Barringer, B. S., M.D., New York.
Bassler, Anthony, M.D., New York.
Bastedo, Walter A., M.D., New York.
Behrend, Moses, M.D., Philadelphia, Pa.
Bell, George Huston, M.D., F.A.C.S., New York.
Bieber, Joseph, M.D., New York.
Bishop, Louis Faugeres, M.D., Sc.D., F.A.C.P., New York.
Blau, Arthur I., M.D., New York.
*Boas, Ernst Philip, M.D., New York.
Bram, Israel, M.D., Philadelphia, Pa.
*Brink, Louise, Ph.D., New York.
*Brown, Mabel Webster, A.B., New York.
Buchanan, J. Arthur, M.D., Pueblo, Col.
Bugbee, Henry, M.D., New York.
Bumpus, Hermon C., Jr., M.D., Rochester, Minn.
Burns, M. A., M.D., Philadelphia, Pa.
Butts, Donald C. A., Philadelphia, Pa.

Campbell, Meredith F., M.D., New York.
Carson, William J., M.D., Baltimore, Md.
Carter, William Wesley, A.M., M.D., F.A.C.S., New York.
Casey, Gertrude U., B.S., Rochester, N. Y.
Clark, L. Pierce, M.D., New York.
*Clouting, Charles A., M.D., London, England.
Cobb, Ivo Geikie, M.D., London, England.
Cooperman, M. B., M.D., Philadelphia, Pa.
Crance, Albert M., M.D., Geneva, N. Y.
Cross, Herbert R., Ph.D., New York.
Culver, George D., M.D., San Francisco, Cal.
*Cumston, Charles Greene, M.D., Geneva, Switzerland.

Dabney, Virginius, M.D., Washington, D. C.
Dailey, U. G., M.D., Chicago.
Dana, Charles L., M.D., LL.D., New York.
Danziger, Ernst, M.D., New York.
Dean, Archie, Jr., M.D., New York.
Deaver, John B., M.D., Philadelphia, Pa.
deRiver, J. Paul, M.D., San Francisco, Cal.
*Diamond, M., D.D.S., New York.
*Donnelly, William Henry, M.D., Brooklyn, N. Y.
Durgin, Delmer D., M.D., Central Islip, N. Y.

Edeiken, Louis, M.D., Philadelphia, Pa.
*Einhorn, Max, M.D., New York.
Ellars, L. Ray, M.D., Louisville, Ky.
Elliott, B. Landis, M.D., Kansas City, Mo.
Elmer, Walter G., M.D., Philadelphia, Pa.
*Erdös, Adolf, M.D., Oradea Mare, Roumania.

Feinblatt, Henry M., M.D., Brooklyn, N. Y.
Feldman, Samuel, M.D., New York.
Follett, E.C., M.D., Washington, D. C.
*Foster, Matthias Lanckton, M.D., New Rochelle, N. Y.
*Fox, Howard, M.D., New York.
*Fridenberg, Percy, M.D., New York.
Fried, Herman, M.D., New York.
Friedenwald, Julius, M.D., Baltimore, Md.
Fuld, Leonhard Felix, LL.M., Ph.D., New York.

Gekler, Walter Albert, M.D., Albuquerque, N. M.
Gibson, J. D., M.D., Denver, Col.
Glasgow, Maude, M.D., Dr.P.H., New York.
Glassburg, John A., M.D., New York.
Glassman, I., M.D., New York.
Goldstein, Hyman, M.D., New York.
Goodall, S. Strickland, M.B., F.R.C.S., London, England.
Goodman, Herman, M.D., New York.
Gordon, Alfred, M.D., Philadelphia, Pa.
Grant, W. S., M.D., Chicago.
Gray, John W., M.D., Newark, N. J.
Greenberg, Geza, M.D., New York.
Gwathmey, James T., M.D., New York.

Hallock, David H., M.D., Southampton, N. Y.
*Hanet-Archambault, G., M.D., Meudon, France.
Harrower, Henry R., M.D., Glendale, Cal.
Hawkins, John A., M.D., Pittsburgh, Pa.
Hayes, William Van Valzah, M.D., New York.
Heyd, Charles Gordon, M.D., New York.
Hinton, J. William, M.D., New York.
Hirsch, I. Seth, M.D., New York.
Horwitz, H. L., B.S., M.D., Chicago, Ill.
House, S. Daniel, Los Angeles, Cal.
Hoyt, Ralph L., M.D., Baltimore, Md.
Hubbard, Ernest V., M.D., New York.
Huhner, Max, M.D., New York.
Hutton, James H., M.D., Chicago.

Jackson, Algernon Brashear, M.D., Washington, D. C.
Jackson, Arnold S., M.D., Madison, Wis.
*Jeck, Howard S., M.D., New York.
Jelliffe, Smith Ely, M.D., New York.
John, Henry J., M.D., Cleveland, Ohio.
Jones, Clement R., M.D., F.A.C.P., Pittsburgh, Pa.
Jones, John F. X., M.D., Philadelphia, Pa.

Kagan, Jonas, M.D., Boston, Mass.
Kagan, Solomon, M.D., Boston, Mass.
Kahn, Alfred, M.D., New York.
Kahn, Morris H., M.D., New York.
Kearney, J. A., M.D., New York.
Keegan, A. P., M.D., Philadelphia, Pa.
*Kerby, Ernest, M.D., New York.
Kerrison, Philip D., M.D., New York.
Kilduffe, Robert A., A.M., M.D., Los Angeles, Cal.
*Knight, C. P., Surgeon, U.S.P.H.S., Canal Zone.
*Knopf, S. Adolphus, M.D., New York.
Kohlman, Samuel H., M.D., Philadelphia, Pa.
Koplowitz, A., M.D., Brooklyn, N. Y.
Krabbe, Knud H., M.D., Copenhagen, Denmark.
Kuhn, I. Russell, M.D., South Fallsburg, N. Y.

Lake, George B., M.D., Oceanport, N. J.
Landsman, Arthur A., M.D., New York.
Larkin, Charles L., M.D., Waterbury, Conn.
Levin, Isaac, M.D., New York.
Levin, Oscar L., M.D., New York.
Levy, Milford, M.D., Baltimore, Md.
Lewis, Dwight M., M.D., New Haven, Conn.
*Lieb, Clarence W., M.D., New York.
Lintz, William, M.D., Brooklyn, N. Y.
Llewellyn, Llewellyn Jones, M.B. Lond., London, England.
Long, Herbert W., M.D., Newark, N. J.
Lussan, André, Bordeaux, France.

McNair, James B., M.D., Chicago.
McNally, William D., M.D., Chicago, Ill.
MacKenzie, Luther B., A.B., M.D., New York.
Maclaire, A. S., M.D., New York.
Maddren, Russell F., M.D., Changsha, China.
*Mayo, C. A., Phar. D. Cincinnati, Ohio.
Meagher, J. F. W., M.D., F.A.C.P., Brooklyn, N. Y.
Meyer, Monroe A., New York.
Meyer, Willy, M.D., New York.
Monroe, P. W., M.D., City of Mexico, Mexico.
Montague, J. F., M.D., New York.
Montgomery, Charles M., M.D., Surgeon (R), U.S.P.H.S., Oteen, N. C.

Waring, J. B. H., M.D., Blanchester, Ohio.
Watson, E. M., M.D., Sheffield, England.
Watson, Leigh F., M.D., Chicago.
Weller, Walter, M.D., New York.
Werdisheim, Leon Heinrich, M.D., Graz, Steiermark, Germany.
White, Francis W., M.D., New York.
White, William A., M.D., Washington, D. C.
Wilensky, Abraham O., M.D., New York.
Wilensky, Sidney B., M.D., New York.
Williams, Charles Mallory, M.D., New York.
Williams, John R., M.D., Rochester, N. Y.
Willius, Frederick A., M.D., Rochester, Minn.
Wilson, George, M.D., Philadelphia, Pa.
Wittenberg, Joseph, M.D., Brooklyn, N. Y.
*Wolbarst, Abr. L., New York.
Wright, J. T., M.D., Mayview, Pa.
*Wright, Jonathan, M.D., Pleasantville, N. Y.

Yeomans, Frank C., M.D., F.A.C.S., New York.
Young, Frank G., M.D., Brooklyn, N. Y.

INDEX TO VOLUME CXIX.

PAGE.

AARON, Charles D.,
(See supplement index.)
Abdomen, mortality in gunshot wounds of. 63
surgical condition of right side of..... 61
Abdominal conditions, x ray diagnosis of.. 492
quadrant, upper right, cause of death in operations on 600
Abortion, bacteriological examination of lochia in 329
febrile 430
quinine in 277
Abscess of brain.....121, 123
of liver, aspiration treatment of..... 226
of lung 189, 191
following aspiration of tooth..... 497
surgical aspect of..... 189
submaxillary, with pneumotyphus..... 385
Abscesses, upper respiratory tract..... 629
Acetonuria in pregnancy..... 430
Acidosis in children.....177, 376
Acne vulgaris 345
Acriflavine injections in gonorrhea..... 629
Acromegaly, associated with adrenal tumor 38
Adenoids, x ray treatment of..... 176
Adenoma of gallbladder..... 63
Adrenal hypotension 57
tumor, associated with acromegaly..... 38
Adrenalin, response to, influenced by thyroid gland 64
vitamine C the homologue of..... 1
Adrenals, effect of, on alkaloids..... 64
functions of 65
importance of, in action of alkaloids.... 476
normal and morbid conditions of..... 64
Affective diseases..... 597
Ahlswede, Edward H. Nonspecific therapy in erysipelas 252
Aikman, John. Infant feeding 356
Airplane tests of hay fever density..... 185
Alcohol, effects of..... 317
Alcoholism in Denmark..... 450
Alexander, M. E. Clinical and experimental observations on blood sedimentation 549
Alkali deficit in nephritis..... 531
reserve of blood plasma during protein shock 278
Alkaloids, action of in relation to adrenal glands 476
Alkalosis in children..... 177
Allergy, treatment of manifestations of.. 309
Allonal, further observations with..... 116
Allport, Frank. Penetrating injuries to the eye in industrial occupations..... 241
Amenorrhea, endocrine treatment of..... 533
Analgesia, synergistic, in surgery..... 69
Anemia, chronic, blood findings in..... 330
following antisyphilitic treatment..... 87
injections of sodium citrate in..... 405
postsyphilitic 87
Anesthesia, local, operations under..... 342
synergistic, in surgery..... 69
Aneurysms, intrathoracic, radial pulse in.. 184
Angina, Vincent's 284
treatment of 605
Animals, use of, in teaching nutrition.... 513
Anorectal operations under local anesthesia 342
Antirachitic and growth promoting functions of certain substances..... 529
Antitoxin in diphtheria..... 178
Anxiety state, drug therapy in..... 331
with endocrine disturbances..... 23
Appendicitis, chronic mononuclear index in 225
errors in home treatment of..... 123
etiological factors in..... 224
infectious, cause and endemic occurrence of 528
Aorta, dilatation of, in children..... 377
Arroyo, Carlos F. Asthenocoria 25
Arsenical compounds in general paralysis.. 454
Arsphenamine, warning against use of in a hemophilic 276
Arterial disease, nitrogen estimations in blood in 330
Artery, cerebellar, occlusion of..... 146
forceps, new 255
pulmonary, atresia of..... 125
Arthritis, endocrine glands in..... 42
metastatic, treatment of 306
rheumatoid, diagnosis of..... 529
thyroid medication in 506
Articulations, injuries and diseases of.... 580
Aspiration treatment of liver abscess..... 226
Asthenocoria, endocrine therapy in 25
Asthma, bronchial 287
complex, myocardial insufficiency in.... 486
etiology of 71
peptone and vaccine treatment of..... 583

PAGE.

Asthma, thymic 65
treatment of..... 309
Atresia of pulmonary artery..... 125
Aulde, John. (See supplement index)
Autointoxication, intestinal..... 597
Automobile fatalities 514
Autotransfusion 121

BAER, Louis. Headaches of nasal origin 400
Bacilluria 478
Bacillus acidi lactici meningitis..... 278
aerogenes capsulatus infection of uterus 278
coli infection of gastrointestinal tract.. 630
of urinary tract..... 308
influenzæ 278
mucosus infection 278
tetanus, in digestive tract..... 278
Back, pain in, significance of..... 62
Bacteria, effect of carbonation on..... 615
Bacteriophages, theory of 528
Bacteriostatic action of acid fuchsin..... 278
Baird, John H. Functional manifestations associated with organic neurological diseases in ex-service men..... 89
Baldness, cause of..... 580
Baldwin, Jane North. Gonads of women from an endocrine viewpoint..... 27
Banting Research Foundation..... 379
Barnes, George Edward. Hypothyroidism, affective diseases, and intestinal autointoxication 597
Barr, Sir James. Bronchitis and its treatment 386
Barringer, B. S. (See supplement index).
Basedow's disease, carbohydrate metabolism in 64
respiration in 43
Bassler, Anthony. (See supplement index.)
Bastedo, Walter A. Medical treatment of duodenal ulcer 381
Bathing, exanthemata from 580
history of..... 406
Beauperthuy, Louis Daniel..... 261
Behrend, Moses. Some problems in gallbladder disease: their operative treatment and complications..... 245
Bell, George Huston. Further observations on the relation of teeth, tonsils and intestinal toxemias to diseases of the eye 239
Besredka's views on immunity..... 614
Bieber, Joseph. (See supplement index.)
Bile, white, in common duct..... 121

BIOGRAPHIES:

Cooper, Sir Astley..... 610
Ehrlich, Paul 510
McBurney, Charles..... 208
Metchnikoff, Elie 450
Mitchell, S. Weir..... 261
Murphy, John Benjamin..... 362
Osler, Sir William..... 312
Rabelais, Francois 408
Scarpa, Antonio 560
Birth control 263
Bishop, Louis Faugères. (See supplement index.)
Bladder stone hindrance to delivery..... 329
tumors, treatment of..... 179
Blau, Arthur I. Use of protein milk in pediatrics 359
Bleeding, therapeutic, in cardiac patients.. 328
Blisters, therapeutic value of..... 323
Blood corpuscles, red, electrolyte content of 330
effect of accessory food substances on.. 530
fat in relation to blood sugar..... 67
findings in anemia..... 330
hemolyzed autogenous, a nonspecific stimulant 531
human, isoagglutinin groups in..... 330
in arterial and kidney disease, nitrogen estimations in 330
in experimental nephritis..... 179
normal amount of in pregnancy..... 127
phosphorus compounds in 330
plasma during protein shock..... 278
preservation of, for analysis..... 279
pressure caused by toxemia..... 314
disorders 57
in life insurance 413
in nephritis 328
influence of insulin on 328
sedimentation 549
serum, sodium and potassium content of 378
sugar, nature of..... 67
picramic acid, methods for..... 67
tetanus antitoxin in..... 278
transfusion, present status of..... 455
Bloodvessels, placental, physiology of..... 329

PAGE.

Boas, Ernest P. (See supplement index.)
Body and mind in good health..... 410
Bodysnatchers 613
Bone diseases following the war..... 582
transplants, formation of pseudarthrosis in 581

BOOK REVIEWS:

Therapeutic Dietetics on Endocrinological Lines with Vitamine C as the Homologue of Adrenin

By CHARLES E. de M. SAJOUS, M.D., LL.D., Sc.D.,
Philadelphia,
Professor of Applied Endocrinology, University of Pennsylvania Graduate School of Medicine.

In an article published in the NEW YORK MEDICAL JOURNAL AND MEDICAL RECORD for March 21, 1923, I recalled that the identity of vitamine C had so far remained unknown and that this was attributable to the fact that the oxidizing enzymes of animals and plants had not been taken into account by biochemists. The cause of this oversight was accounted for by the fact that physiology, though it had contributed much to our endocrinological knowledge, had failed to identify the functions of the adrenals, the main organs involved in the present connection. It was shown, moreover, that my interpretation of these functions (1903) based on a collective study of all branches of medicine including physiology, had stood the test of time while accounting for experimental and clinical results which no other interpretation could explain.*

The purpose of the present paper is to submit the results of a series of comparative tests—approximately one thousand—calculated to identify those foods in general use which supply vitamine C in a form similar to that used by the human organism. This could only be done by comparing the results of two tests: one affording a positive reaction with any of the many oxidases found in edible plants, the other giving the positive reaction only when the oxidase corresponded with one which, as will be shown, exists in human blood. The influence of cooking was also tested. The practical bearing of these researches will be suggarized under specific headings.

In the above mentioned paper I submitted that the adrenals were the source of vitamine C, and that this substance, as the homologue of adrenin, epinephrin or adrenalin (pharmacological synonyms), was a paramount factor of tissue life, i. e., the agent which, in the red corpuscles, as a component of hemoglobin, furnished oxygen to all tissues. This same substance was then found, by tests presently to be described, in greater or less quantities in certain foods, fruit, vegetables, meats, etc., thus making it possible, through these foods, to increase the efficiency of the blood's hemoglobin as an oxidizing agent. The farreaching meaning of this fact asserts itself, particularly in view of the inability of physiologists so far to explain tissue oxidation, the function involved in the process. Thus, as Professor Halliburton, of London, states in the latest (1921) edition of his *Textbook of Physiology:* "Knowledge of tissue respiration is so scanty that we can say but little about its pathological bearing."

The connection between the adrenals, tissue oxidation and metabolism, which I urged over twenty years ago, is no longer to be doubted, in view of the array of confirmatory data published by investigators since, including the recently observed influence of these organs on basal metabolism. Nor should the effects of foods upon them be overlooked. Recalling, for instance, that McCarrison had found "marked pathological changes in the adrenal glands due to unbalanced diets," W. J. M. Scott (1), in charge of the laboratory of surgical research at Harvard, found that after partial adrenal insufficiency experimental animals were susceptible to dietary factors which produced no symptoms in normal animals. He states, moreover, that "the effect of diet in adrenal insufficiency is an important problem which should be carefully studied."

In the present paper I shall submit only a succinct review of the evidence which led to the conclusion that the vitamine C of foods was the homologue of the adrenal medullary product, including its active principle epinephrin or adrenalin. The personal researches (1903) referred to above had shown that the adrenals secreted a substance which, on traversing the lungs, took up the oxygen of the air and became an oxidizing enzyme which I termed adrenoxidase. This oxidase, or catalase, I found to correspond, in its biochemical properties, with a plant oxidase long known as tyrosinase, the oxidizing en-

*This applies also to the experimental data recorded by Professor Pende, of Messina, Italy, in his article published in the NEW YORK MEDICAL JOURNAL, for October 17, 1923.

Copyright, 1924, by A. R. Elliott Publishing Company.

zyme of tyrosin. Being water soluble and closely related to the alpha aminoacid of hydroxylphenylproprionic acid, it justified, in view of its importance in the vital process and its identity as an amine, the term "vit-amin" introduced by Casimir Funk. The connection of this antiscorbutic vitamine with the adrenal medulla was emphasized by the experimental observation of McCarrison (2) in scorbutic guineapigs that there was "a marked diminution in the adrenal content" of the adrenals.

Sustaining the personal conclusion that adrenalin, as adrenoxidase, was the homologue of the food ferment tyrosinase (vitamine C) were the facts that the bronzing of Addison's disease is often associated with the ferment tyrosinase (3); that the hematoidin found broadcast in animals after removal of both adrenals, particularly in rats (4), is likewise connected with it through a product of broken down hemoglobin; that adrenalin is also found in large quantity in the skin glands of toads (5) which structure, as we know, takes part in the respiratory process of batrachians; that tyrosinase is also found in the macerated skin of frogs and toads (6, 7), and that tyrosin has been considered as "the mother substance of the melanins" which, as is well known, cause the bronzing of Addison's disease. That tyrosin and adrenin were similar bodies seemed clear.

Additional confirmation was afforded by the striking concordance between the results of biological tests, as carried on in guineapigs and other animals by the British Medical Research Committee (8) and other observers and those obtained in considerably over a thousand personal observations (all repeated and amplified for the present paper) based on two color tests devised for the purpose. One of the latter repeats in foods containing vitamine C, the identical function adrenin carries on in the body or in the laboratory: it endows the homologue of the hemoglobin —the tyrosin of plants—with the power to take up oxygen and becomes red, as venous blood does when in the laboratory it is treated with adrenalin (9, 10, 11) under appropriate conditions of osmosis and temperature.

VITAMINE C TEST.

This test is carried out as follows: The food is crushed, or rasped, and finely broken up and its fluid carefully mixed with it, or very little water added if dry. A few drops of the 1-1,000 adrenalin chloride solution is then poured upon it and mixed in; then a few drops of a solution composed of one part of the three per cent. hydrogen peroxide solution to nine parts of pure water are also poured on. When mixed in a test tube the two solutions cause no change of color; it is only when a tissue or fluid, animal or vegetable, contains the oxidizable body that the reaction occurs. The strength of the solution should not be modified as enzymes are very sensitive to oxidizing substances. This test, which appears to be specific as a counterpart of the physiological respiratory process in animals and plants, I have termed the "adrenin-H_2O_2 test." The old maxim that "one cannot draw blood from a turnip" seems compromised in this connection, for a fresh juicy turnip will, under this test, appear in less than one hour literally "bloody," the red magma turning brown by the next day, thus indicating the biochemical connection with the Addisonian bronzing.

A nonspecific color test which I have termed the "guaiac-H_2O_2 test," is very serviceable as an adjunct. It differs only from the former in that tincture of guaiac is used instead of the adrenalin solution. The technic is the same. When tincture of guaiac is applied, as shown by Planche in 1810, to many organic tissues and fluids, it causes them to assume an amethyst blue or bluish green color. Their oxidases (there are many kinds) merely oxidize the guaiac. This may be repeated in the test tube by mixing some of the tincture with the one in ten hydrogen peroxide solution. A curious feature, however, is that when both are applied, as used in the test tube, to tissues, these respond differently. Thus mutton will give ++++ the highest, and pork but + the poorest, vitamine C reaction. Cooking also modifies its effect; thus, spinach gives +++ when raw and nothing when boiled. Even the different parts of the same food used may respond differently. Thus chicken dark meat gave +++ and the white meat O. While it is probable here that the process involved is one of reduction of the H_2O_2 added by the food tissues, the fact remains that it presents the important characteristic of corresponding closely in its results with both the biological and adrenin tests. Thus, all three, the biological, adrenalin-H_2O_2 and guaiac-H_2O_2 give the potato ++. The guaiac-H_2O_2 test is particularly serviceable where, as in red meats, strawberries, beets, etc., the juices are red; it may also replace or serve as control for the adrenin test as regards the actual presence of oxidases.

The food values in vitamine C, as determined by the two color tests given in the following charts, were obtained *before* comparison with the results recorded by the British Committee and other observers were consulted.

In practically every instance, the estimated value in + signs was established by two persons besides myself to avoid any misinterpretation of the shade observed. The results are tabulated on page 3.

Vegetables.—In these, the biological and two color tests for vitamine C corresponded in practically every instance. The only two exceptions were due to various causes. In the carrot, the fact that only the juice or dried carrots were used in the biological tests accounts for the low rating. As to onions, guineapigs in my experience invariably refused the round onion. It is probable that in the biological tests recorded, the animals consumed very sparingly of them. In accord with Hess's biological tests the tomato proved, under color tests, very active, as shown in the chart.

As to cooking, the boiling point was found to destroy the reactivity of vegetables soft in texture, vitamine C being water soluble, while tyrosin is destroyed when heated at 67° C. or above. Cooking below this temperature, i. e., at 65° C., reduced their reactive value of the guaiac-H_2O_2 test about twenty-five per cent., while the adrenin-H_2O_2 retained its full value. The vegetables which stood cooking best were those dense in texture, such as the carrot, turnip, etc., and those protected by a covering, such as peas and beans.

Fruit.—Both color tests agreed as regards the food value of fruit as carriers of vitamine C. The biological and color tests agreed in the case of Florida

oranges, while California lemons corresponded with the Mediterranean lemons found alone by Alice H. Smith to possess, in Europe, antiscorbutic properties. The limes—Costa Rica limes—were also found to give a positive reaction, unlike those tested biologically in Europe.

Dairy products.—Whole milk showed a lower reactive power than skimmed owing to its cream; this applies also to icecream. But the difference is shown only by the adrenin test, owing to its specificity. Buttermilk should, like skimmed milk, give a high reaction, but churning accounts for this discrepancy,

exposure to air oxidation, as shown by Hess and others, impairing greatly the efficiency of milk, even during pasteurization.

Salads.—The only food of this class tested biologically was lettuce. But all those tested by the color tests also gave high reactions, thus illustrating their value as sources of vitamine C.

Bread, cereals and nuts.—The comparative color tests were rarely concordant, to the detriment of bread and cereals. But few biological tests seemed to have been made in this series, but the "staff of life," bread, showed negatively in all tests, doubtless due to the action of heat. This was also a result of the destructive influence of prolonged baking. Suggestive in this connection is the fact that of many wheat crackers tested, only one gave a positive reaction, the saltine. Inquiry elicited the fact that they were exposed but a very short time to a very high temperature. Again, cornbread gave a reaction above the normal one for corn, but it was found to contain milk. Cornmeal mush, however, gave nothing; it had been boiled. Nuts gave a poor adrenin reaction but a rich guaiac reaction.

Meats.—In these, the biological and color tests disagreed, but when we realize that the meats tested biologically (which were unspecified and termed lean meat) were fed to herbiverous animals, the biological tests seem faulty. The results have, in fact, surprised some observers, owing to the high exothermic reaction of muscular tissue. Because of the red color of meat fluids, the adrenalin test was deemed liable to mislead and not used in the tests; adrenoxidase being their normal enzyme anyway, the guaiac H_2O_2 reaction was deemed sufficient.

Some interesting facts developed with regard to cooking. Boiling reduced mutton and dark chicken meat seventy-five per cent., but raised lamb fifty per cent., as did also broiling and roasting. Broiling and roasting also improved beef twenty-five per cent., and veal fifty per cent. Pork gave the lowest reaction, but ham and beef tongue—both smoked and salted meats—surprised us with a ++++ even after boiling. This affords an important hint as regards meat preservation and actual improvement in vitamine value, for which no clear explanation can as yet be vouchsafed.

Molluscs and fish.—These showed considerable reactive activity and perfect correspondence as regards color tests, no biological tests having apparently been used. All reactions, however, were annulled by boiling.

Soya beans.—These afforded surprise, as had meats, for they also had been found negative as a class in biological tests, owing probably to the large proportion of oil they contain. Both color tests not only indicated that they are rich in oxidizing enzyme but also that five varieties contain tyrosin, as shown by the adrenin-H_2O_2 test. While boiling annulled these virtues, they were not impaired by heating below 67° C.

Chlorophyll.—Many plants, including grasses other than those used as food also gave positive results, thus suggesting that they might be used as sources of vitamine C in the absence of citrus fruit and green vegetables in the dietetic treatment of scurvy, anoxemias and allied conditions. Prof. Bürgi, (12) of Berne, has urged the therapeutic value of chlorophyll, so widely distributed in plant life. He gives as example spinach, which contains chlorophyll in large quantities and which, we have seen, gives a strong positive adrenin-H_2O_2 reaction, as a food for the elaboration of hemoglobin. Even here a direct link with the adrenin asserts itself. J. F. Fulton, Jr. (13), in a study of blood chlorophylls, states moreover that "recent investigations have shown that hemoglobin and chlorophyll are similar chemically," and recalls the investigations of Gortner on insect melanins—to which we have seen the bronzing of Addison's disease is due—to the effect that "they are sometimes formed from the chlorophyllous substances (oxidizable chromogens) acted upon by the plant ferment tyrosinase"—the homologue, as I have shown, of adrenoxidase the oxidizable substance and chromogen of which is adrenin, the isomer of vitamine C.

CLINICAL APPLICATION.

The Anoxemias.—The identification of vitamine C by differential tests enables us to guide intelligently the use of foods which influence tissue oxidation and control it where needed. It seems to me to inaugurate, in this particular phase of cellular chemistry, a system of dietetic therapeutics on scientific lines. Its field is unlimited, since all tissues, including the blood, are the seat of oxidation processes in which perfect equipoise in this respect is a *sine qua non* of functional efficiency. Again, while increased oxidation is beneficial in certain disorders, it is harmful in others. Defensive efficiency, for example, is closely associated with adequate oxidation, as illustrated by fever, while hyperpyrexia, with its possible consequences, hemolysis and autolysis, typifies the morbid effects of excessive oxidation. Judicious dietetics afford a potent aid to rational medication in these circumstances, vitamine C foods, selected and adjusted to the needs of the moment, being capable often of deciding the issue in a threatening case.

Of course, vitamine C represents but one of the series of three sufficiently studied so far to warrant their general recognition as separate agents of this class, the other two being the fat soluble or antirhachitic vitamine A and the water soluble antineuritic or antiberiberi vitamine B. The relative importance of vitamine C may be surmised, however, when, as the intermediary upon which the body depends for its oxygen, it is rendered unable, by toxic asphyxia, strangulation, etc., to take up oxygen from the air in the pulmonary alveoli. Death ensues within a short time. Again, as the antiscorbutic factor, the water soluble vitamine C protects the body against scorbutus and infantile scorbutus or Barlow's disease. Identified as adrenin, i. e., as the oxidizing agent of the adrenals, the production of this disease becomes clear: scorbutus in the adult or child is a manifestation of advanced oxygen deprivation, i. e., anoxemia, plus a secondary infection due to the resulting loss of defensive efficiency. If the symptomatology of scorbutus is recalled with this fact in mind the primary cause of the gradual tissue death will become plain, i. e., cellular asphyxiation.

True, advanced scorbutus as suggested by the term scurvy is seldom seen in everyday practice. Milder forms of anoxemia are, however, observed daily in our work in all conditions in which the blood cells are more or less impaired, the anemias for instance,

pallor both in children and adults being often the index of deficient ability of the red corpuscles to take up oxygen from the air in the lungs. The heart and muscular layer of all bloodvessels being insufficiently oxygenized from the same cause, become dilated or relaxed. The pallor may then become marked, as often observed in the inadequately fed children of the slums. The vascular dilatation may be such, in starvation, as often observed during the world war, as to lead to edema, children appearing fat though pale when in reality they were only waterlogged.

The list of diseases in which anoxemia is a prominent pathological factor is a long one; a few only can be mentioned within the precincts of this article. It includes several ubiquitous disorders which are virtually never ascribed to such a cause. Constipation, for instance, is often due to atony of the intestinal muscularis through the same cause which induces pallor in ill fed children and edema in the starved. The participation of oxidation in the process is soon shown by the use of intramuscular injections of epinephrin even in the edemas or ascites of hepatic scirrhosis. Even after the removal of gallons of fluid, the ascites will often not recur. Gastroptosis and enteroptosis are not infrequently associated with anoxemia and the beneficial use of strychnine—an adrenal stimulant as I showed in 1903 and 1907 (14), a fact confirmed by Stewart and Rogoff (15) in 1919—attests to the adrenal rôle of adequate oxidation in the process. The gastric atony leading to persistent vomiting following sometimes severe surgical operations, parturition, and late in various severe infections, typhoid fever for example, and due to adrenal failure, likewise entail relaxation of the gastric muscularis, intense myasthenia, and threatening heart arrest in diastole, all due to anoxemia in which failure of the adrenals plays a leading role. Bronchial asthma is also in part (for the deficiency of oxygen is, of course, but one of the prominent factors of all morbid processes) due to anoxemia; hence the immediate relief afforded by adrenin injections. Neuralgia has been described as a "nerve crying for blood," but it is sufficient oxygen which is lacking to carry on efficiently its local metabolic processes and prevent the local accumulation of toxic wastes.

Defensive efficiency during disease.—Much valuable work is now being done to place on a solid foundation the principles of immunity as applied to the prevention of acute infections. Practically no effort is made, however, to sustain or enhance during disease, the defensive efficiency upon which the preservation of life depends. Year in and year out during the forty-five years of my clinical experience have textbooks of practice recommended therapeutic measures addressed to symptoms alone, with "specifics" in a very limited number of disorders, to prove the rule that in practically every instance the course of the disease *per se* is left to itself. The diet is still a sort of perfunctory affair in which no attempt is made to compensate for the materials consumed during the greatly increased metabolic activity which the defensive process entails, as indicated by the elevated temperature, the greater output of carbon dioxide, the correspondingly augmented intake of oxygen, etc. Vitamine C foods become almost sheet anchors in this particular phase of the defensive functions. They serve to replace as fast as used, the adrenin factor upon which the supply of oxygen depends, thus insuring all cells and fluids their defensive integrity as far as oxygenation is concerned. Moreover, with very few exceptions, eggs, for example, the presence of vitamine C betokens the presence of vitamines A and B, thus affording in all foods shown by the biological and color tests to contain C in the foregoing tables, the three essential vitamines for any given case.

An essential feature brought out by the cooking tests, however, is the destructive effect of boiling upon the tyrosin of practically all foods. But most of those used for the sick need not be boiled. The integrity of tyrosin is preserved—thus insuring the efficiency of the vitamine C when the cooking is kept below 67° C. Milk need never be heated beyond this point. Whole milk, we have seen, gives a lower adrenin value than skimmed milk; this is because it is relieved of much of its cream, the vitamine C being left in the remaining fluid. If well borne, however, unskimmed milk which is rich in the antirachitic vitamine A is to be preferred. In rachitic children it is particularly useful, adding lime water to provide calcium. If, as in some institutions, skimmed milk is alone available, butter and egg yolk may serve to contribute, the former A and the latter A and B vitamines. Orange pulp and juice, so rich in C, also contains B vitamine though in smaller relative quantity. Certain meats show enhanced vitamine C values, we have seen, when broiled. Such meats afford food rich in vitamines when finely hashed, if such can be done; if not, its expressed juice may be used advantageously as it is, or the juice may be used to make soups. Vegetable purées may be employed to advantage in this connection, for even if the vegetables have to be boiled and their vitamine C destroyed, their alkaline salts are as important to the patient's welfare as the vitamines themselves. These few hints will suffice to illustrate a line of thought upon which a whole volume could be written when the active principles of A and B and McCollum's very promising vitamine D are also known.

It should be borne in mind in this connection that many articles used as food contain no vitamines as far as the biological and color tests available make it possible to discover. We have seen that several, such as eggs, polished rice, lobster, for instance, give no C reaction even when tested raw, but others, such as lard, oils, even olive oil, cocoa butter, margarine, egg substitutes prepared from cereals, custard powders, etc., are devoid of the three vitamines. Wheat bread and crackers, due to their exposure to baking heat, also belong to this category. That all such should only be used as adjuncts, in the sense that some may be used for the alkaline salts they may contain, is self evident.

Calories.—The question of calories or heat units as evidence of the relative values of foods is intimately bound up with the vitamine problem. The calory doctrine, however, is steadily losing ground. As recently (1923) stated by an authority on dietetics, C. B. Farr (16): "Of late the caloric method of expressing food vaules has somewhat fallen into disrepute. This is partly a reaction from the exaggerated emphasis formerly given to the method,

to the exclusion of older ideas in reference to the proper balance of the principal foodstuffs. It was only the discovery of the vital differences in various proteins, the essential character of minute amounts of accessory food substances and the full significance of mineral salts that recently swung the pendulum in the opposite direction."

Another source of weakness in the present connection is that the calory doctrine fails to take into account food factors which perpetuate the well being of the body. Thus a food apparently quite adequate in calories may in the long run prove harmful owing to its deficiency in vitamines. Clinicians are often told by advocates of the calory method, for instance, that the greater quota of nourishment in a meal lies in the bread and butter eaten. But we have seen that wheat bread, as shown by both biological and color tests, contains no vitamine C, while butter supplies only vitamine B. It would seem, therefore, that the balance of the meal is needed to supply vitamines A and C. It is probable that the calory doctrine will come into its own when all factors concerned with thermogenesis will be better understood. In the present stage of knowledge, however, it is a dangerous method for dietetic treatment of the sick, one capable in fact of favoring a fatal issue unless the need of vitamines (and mineral salts) capable of sustaining the vital and defensive functions of the body is also recognized and met.

Pluriglandular Therapy

By IVO GEIKIE COBB, M.D.
London

The physician who prescribes pluriglandular preparations is a bold man and one to be pitied. For he will be scoffed at for the theory which underlies his treatment, and he has a difficult task to perform in selecting the ingredients of his prescription.

There is little, if any, laboratory support for many of the extracts which are found in these compounds, but this is not tantamount to saying that they are useless or inert. Let us never forget that thyroid substance was proved by its clinical results rather than by laboratory findings. There are several cogent reasons why organic extracts should be of value, and recent researches have revealed possibilities hitherto unsuspected.

The clinical results of preparations of such organs as the thyroid, pituitary, and suprarenal gland are too well established to require any discussion here; although the question of whether all three have any therapeutic properties when administered by the mouth is not settled to the satisfaction of all workers. Their employment by the subcutaneous or intramuscular route produces results which leave no room for doubt as to their potency. It may also be admitted that the activity of pituitary preparations when given by mouth is beyond dispute, although the smaller doses which have hitherto been employed appear to be followed in some instances by no definite results. Pituitary feeding in suitable doses—and these may often have to be very large—has a definite and well established effect on metabolism; and the results of many clinicians support this contention. Suprarenal gland substance—both cortex and medulla—is also given by mouth. There are two reasons why this substance has not been as widely utilized by mouth as other glandular extracts; first, because its hypodermic use and local action overshadow more remote results when given by mouth; second, because the average suitable dose by the oral route has so far been undetermined.

In this paper it is proposed to consider the employment of pluriglandular preparations, the theory underlying such prescribing, and some clinical results.

It is only in recent years that administration of pituitary substance has been at all widely utilized; and even now the data relating to anterior pituitary organotherapy are lamentably deficient. This is partly due to the custom of using whole gland preparations, and partly, no doubt, to the gaps in our knowledge of the composition and chemistry of the pars anterior. Robertson has isolated a chemical constituent of this part of the gland, which he has named *tethelin,* and which he regards as the growth controlling principle. It is a lipoid, and is believed to be rapidly decomposed in the alimentary canal. To this characteristic may be due some of the uncertain effects of anterior pituitary organotherapy.

We shall refer at a later stage to some of the uses to which the pars anterior has been put in therapeutics. We may mention here, however, that there is laboratory evidence to prove that orally administered pars anterior produces definite effects in animals.

All workers in the organotherapeutic field are familiar with the difficulty of arriving at a decision as to what preparation to utilize, when commencing treatment by means of pituitary substances. On the one hand, it is almost universally believed that posterior pituitary substance is inert, when given by the mouth; while there is ample evidence, on the other hand, that whole gland pituitary organotherapy is an exceedingly efficacious weapon in many and varied disorders. It is exceedingly difficult to decide which part of the gland is at fault in a given case, and this has led in many instances to the choice of preparations of the whole gland when pituitary substance is prescribed. Among the well known uses of whole gland substance are the later stage of acromegaly, tumors and enlargements of the pituitary gland, epilepsy and pituitary headaches. The paresis of the bowel which sometimes follows anesthetics, occurs in the course of lobar pneumonia, and is occasionally seen in chronic invalidism from any cause, yields rapidly to the hypodermic administration of pituitary substance.

There are some disorders, however, in which anterior pituitary therapy is the method of choice, and there are conditions believed to depend upon hypofunction of the pars anterior. Foremost among such states is dystrophia adiposogenitalis, which has been reported by many observers to be favorably influenced by the administration of anterior pituitary substance. Some clinicians, however, combine other organic preparations with that from the anterior pituitary; one observer combining thyroid and ovarian with the hypophyseal substance, and claiming that it caused a redistribution of fat and an improvement in the sexual development. Whole gland pituitary substance has also been employed in these cases, but the majority of observers lean to the use of preparations of the anterior pituitary.

In considering pluriglandular therapy, we have first to decide whether the substances contained in a mixed product are such as will exert any effect whatever when taken by the mouth. In this article, we are concerned with oral therapy, as pluriglandular prescribing by any other route is little utilized.

We shall briefly refer to several organic substances, considered from this standpoint, and then discuss their application in pluriglandular form.

Thyroidin needs brief reference only. Its action is well known, in fact fresh uses are still being discovered for this substance. As the part of the thyroid gland in the bodily functions is becoming better understood, so its utility in a wide range of disorders is being established. Combined with pituitary substance, it forms a decidedly popular prescription, and is successful in many conditions, which appear to depend upon a hypofunction of one or both of these regulators of metabolism. There is no need to spend further time in discussing thyroid therapy, as I dealt with this subject in some detail recently (1). We shall turn, therefore, to its smaller, but in many ways equally vital neighbors, the parathyroids.

The first point which is of interest in this connection is that parathyroid substance has been shown to exert a definite action when administered by the oral route. Apart from glandular implantation, its employment by the mouth is at least equally efficacious to its hypodermic use.

The effects which follow parathyroidectomy in animals have suggested what may be the symptoms of parathyroid deficiency in man. Beyond this we are unable at present to go, although Hurst has put on record a case of parathyroid deficiency, which was cured by the oral administration of parathyroid substance. From the laboratory evidence, as well as from the clinical findings, this form of organotherapy would seem to be most useful in spasmodic conditions. It has therefore been tried in such disorders as epilepsy, eclampsia and chorea. There is no evidence that these diseases are connected with the parathyroid gland, so that any beneficial results noted must be regarded as due to the pharmacological action of this substance, rather than to its substitutive use.

Some observers have reported favorably from its use in the conditions just referred to, and, indeed, there is some reason why it should be beneficial, seeing that absence of parathyroid produces a state characterized by nervous instability and tremors, while epilepsy, chorea, and eclampsia share, in common with tetany, symptoms of this nature. Italian physicians perhaps more than those of other countries have been favorably impressed with their clinical results with this substance.

I, while frankly sceptical of the organotherapeutic properties of some of the substances to be found in manufacturers' catalogues, incline to the opinion that parathyroid substance will prove to possess a wider and more successful applicability than has hitherto been the case. It has been used in the tremors of the neuroses—more especially in paralysis agitans; in socalled anxiety conditions, in Graves's disease, in tachycardia, and in hyperpiesis. Combined with thyroidin it is reported to be useful in healing chronic varicose ulcers. Turning for a brief space to the theories which have been advanced to explain tetany, we find that three hold the field. These are, a decreased calcium deficiency, leading to neural irritability; an alkalosis; and the accumulation of methylguanidine, presumably due to the loss of parathyroids. Experiments have shown, however, that the onset of tetany varies according to the temperament of the animal. If the animal is pugnacious, and controlled largely by its basic instincts, the mortality from tetany is high, while in animals who have been handled gently for several generations the mortality is relatively low.

These results are interesting, as they are suggestive of the cause which underlies the long continued disturbances of the endocrine system which have resulted from the war. Here there were factors which bring to the surface instinctive reactions normally relatively dormant. It is not stretching the point to suggest that the war neuroses owe their resistance to treatment largely to the fact that endocrine disturbance succeeded disturbance of the mental equilibrium. As parathyroid substance can—certainly in some individuals—be absorbed from the digestive tract, and rectify errors of function, so we

shall probably see a more extended use of this hormone, when its properties and doses are better understood.

When we turn to a usual component of the pluriglandular prescription, namely, one or other of the genital glands, we realize at once that here is indeed a controversial subject. From the days of Brown-Séquard, testicular organotherapy has been the field upon which many a battle has been fought. Opposed to the enthusiastic assertions of Brown-Séquard, was the scoffing incredulity of his contemporaries. In the days in which we live, the optimistic paragraphs of manufacturers' catalogues are countered by the "not proved" verdict of the laboratory. The physician whose main work is the amelioration of the symptoms of his patients, turns to the manufacturers hoping their statements are correct, while the physiologist's warnings come as a chill blast to his new found therapeutic faith.

To decide between the manufacturers' assertions —many of which are founded purely upon empirical grounds—and the statements of the scientific investigators, is no easy task. For the latter tells us there is no laboratory support for the oral administration of, let us say, adrenal substance; while the former quotes from authors who have successfully utilized it in the treatment of disordered health. It is obvious that the *post hoc* argument is always available, when we are dealing with the living human subject. It is this fact which causes the accurate mind of the scientist to doubt the optimistic reports of the clinician.

In dealing with a subject such as this, we can best serve the reader if we warn him against accepting any statements as to the action of any organic substance, which contradicts accepted physiological facts. If a clinical report does this, it is indeed to be doubted. But where it is unsupported by laboratory proofs, nevertheless it may be right.

With this digression let us study the generative organs under three headings, as these will include those substances it is worth while to consider, namely, orchitic, ovarian, and prostatic substance.

Testicular extract, in spite of the unenviable prominence which it still receives, would nevertheless seem to be of considerable value. Transplantation experiments and operative procedures have proved beyond a doubt that the testicle possesses an internal secretion: and feeding experiments on animals show that it is absorbed by the oral route. Moreover, when it was administered to female chickens and pigeons the animals developed male characteristics.

Allowing, therefore, that properly prepared extracts are utilized, and the dose is regulated to the individual case, testicular extracts may be regarded as a legitimate component of a pluriglandular preparation. From the viewpoint adopted in this paper, this substance conforms with the standard in that an extract of the testicle contains an internal secretion, and this secretion is believed to be capable of absorption when administered by mouth.

Ovarian organotherapy is deserving of sympathetic consideration, if only on account of the excellent clinical results which have been reported from many quarters. It is important to consider it here in some detail, because its utility in combination with other organic preparations is very wide, and because the ovarian secretion is so intimately linked up with other of the regulators of metabolism, that it lends itself singularly well to embodiment in a mixed glandular prescription.

First, what is usually implied by the term ovarian extract? Fresh ovarian substance, derived from the ovaries of cows or pigs, and with an approximate dose of five grains, is what is meant. This may be administered in tablets or capsules by the mouth, or in a sterile liquid form for subcutaneous injection. Some workers in this field, however, lay stress upon the importance of an extract of the corpus luteum, as likely to contain the most active internal secretion of the organ. Other workers have isolated two different substances, both active physiologically and mutually antagonistic in their effects. Statements are made that an extract of the corpus luteum has the power to regulate menstruation, to increase the flow where this is pathologically scanty, and to inhibit excessive loss where this is occurring. The work of one school, however—the investigators who have isolated two antagonistic autacoids—suggests that one hormone stimulates the catamenia, while the other checks it. This may explain the assertion apparently somewhat paradoxical—that extract of corpus luteum regulates menstruation.

But little that is definite can be stated with reference to whether the ovarian extract should contain luteal substance or not. One observer, whose work on this subject entitles him to respectful attention, believes that the presence or absence of luteal material is of no great import. On the other hand, another investigator is loud in his praise of an extract of corpus luteum, as opposed to whole ovarian substance. One other variety should be mentioned, namely, ovarian residue. This consists in an extract of the ovary after removal of the corpora lutea.

It is not possible to dogmatize at present, as to which of these preparations possesses the greatest activity. That some definite clinical results may be expected from ovarian organotherapy is certain, in a fair percentage of suitable cases.

There are certain facts known about the prostate gland, which make it likely that it possesses an internal secretion, apart from its better established functions. It is an interesting fact and one worthy of notice, that this gland tends to hypertrophy only when the testicular secretion is on the wane: and it has therefore been suggested that prostatic overgrowth —apart from tumor formation—may be in the nature of a compensatory hypertrophy.

Certain experiments have suggested that prostatic-fed tadpoles grow faster than controls, and atrophy of the testes has been noted to occur in rats from whom the prostate had been removed (Macht and Bloom). These and other facts make it likely that the prostate has an internal secretion, which enters into the socalled hormone balance, but nothing definite is as yet known on this point.

It is referred to in this paper for two reasons, first, because its clinical use appears to be extending, and because it has found a place in certain pluriglandular preparations. Second, because there is practically no literature on the endocrinological aspects of this gland: it would possibly repay the time and labor expended if some clinical reports could be furnished as to the results of treatment by prostatic substance, both in local disorder such as hypertrophy, and in

more general states of ill health, such as are associated with disorders of the functions of other of the organs of internal secretion.[1]

No account of pluriglandular therapy would be complete without some reference, however brief, to other extracts which are frequently incorporated by manufacturers. I have tried, in writing this paper, to select those tissues which are most usually to be found in the catalogues of chemists who furnish organotherapeutic products. I have seen it stated, usually by experimental physiologists, that with the exception of the thyroid gland, no other organic preparation is of the slightest use as a substitutive agent. We are all, unfortunately, familiar with the disappointments which have met us in attempting to treat Addison's disease by suprarenal gland substance. Equally unsuccessful has hitherto been the employment of pancreatic substance in metabolic disorders such as diabetes.

Let us, however, keep clearly before us this fact, that while substitutive therapy has few clearly proved successes to claim, fresh fields are yearly being opened, as is evidenced by the recent work on pancreatic extract, which has resulted in the isolation of insulin from the islands of Langerhans. But this is only one aspect of organotherapy—that usually called substitutive. Many organic extracts, many tissues derived from various organs, are therapeutically active, and possess definite physiological properties. As an example of this, we may quote the effect of pituitary extract upon the uterus, and its well recognized action in paralytic distention of the bowel. I am far from joining the ranks of those who see nothing in organotherapy but a field for the manufacture on a large scale of fresh products for the practitioner to prescribe. But it does seem wise to issue a warning that not all the substances which appear in catalogues are as active as we are sometimes led to suppose.

Mammary substance is an example of this. I have good reason to believe that feeding on mammary substance exercises a control on menorrhagia. When we turn to the catalogues, we learn that it is invaluable for this action: the author of a recent book dealing with organotherapy, however, dismisses mammary extract as of little import.

The claimed action of the mammary gland substance concerns two main functions, its use as a lactogogue, and its inhibitory action on the catamenia. The former is a subject on which there is considerable disagreement, although it is fair to say that not a few clinicians are convinced of its activity. I have already referred to its second action; with one more reference, we will leave the subject. It is asserted by some workers that its exhibition to patients suffering with uterine fibroids causes a diminution in the size of the tumors. Of this I have had no experience.

The placenta, having physiologically strong claims to recognition by endocrinologists, has received some degree of attention. It has been argued that a hormone is elaborated by the placental tissue, whose work is the preparation of the mammary gland for lactation. Placental extract has therefore been administered to nursing mothers whose milk was scanty. Several observers have reported favorably, after clinical experience in an adequate number of patients who have been treated by the oral administration of placental extract; some have not been certain enough to express a definite opinion as to the results; while still others are frankly disappointed.

Considerably more evidence is needed before placental extract is deserving of admission as an active organotherapeutic agent.

The thymus has been indicted with many crimes, among those being the accusation that it is *particeps criminis* in Graves's disease. As thymus substance is a not unusual ingredient of the pluriglandular prescription, a few words as to its action and use may not be out of place.

The exact rôle of the thymus in Graves's disease has not been determined. On the one hand, it is stated that this gland is enlarged in this disease, and that the disease has improved after thymectomy. Against this must be put the reports of cases of the same disorder which have improved definitely on thymus feeding.

Thymus medication has also been employed in myxedema, delayed development, marasmus, acromegaly, rickets, dementia precox, and Addison's disease. Reports of the results of thymus feeding in such diseases as these, suggest that the proceeding is occasionally followed by marked success, sometimes by amelioration of the symptoms, and in some cases by failure.

As no hormone has been obtained from this organ, any organotherapy must rest purely upon empirical grounds.

In view of the recent work on the pancreatic secretion and the possibilities attaching thereto, it is not proposed to consider the internal secretions of digestion here.

When we come to consider such substances as extracts of nerve tissue, of the brain, spinal cord and sympathetic ganglia, we are inclined to scoff at the ignorance which suggests their inclusion in any mixed gland preparation. To give extracts of the cerebral cortex to patients suffering from a psychoneurosis is surely atavistic, and is harking back to the era of incantations and sorcery! But, unless one is prejudiced, not even this prescription, foolish and fatuous as it seems, can be dismissed as easily as this. Voltaire said, *"L'art est difficile, la critique est facile."* The art of treating disease is indeed difficult, however easy it may be to jeer. Can there be any solid groundwork of reason for prescribing nervous tissue? Does it contain any substance specific to itself, and if so, can this do anything physiologically or where abnormal states exist?

So far as we know at present, this tissue is rich in lipoids, and according to some observers there is reason to believe that a lipoid is specific to the tissue from which it is obtained. There is little reason, however, for the wide use to which neural extracts are put, and it is the indiscriminate, irrational and wholesale use of substances such as this which does the practice of organotherapy no good.

Before concluding this paper, let us take at random

[1] I have recently encountered in the literature on this subject an interesting account by Hoxie of a case in which prostatitis was associated with submanubrial dullness, which latter was ascribed to thymic hyperplasia. The general symptoms were those of myasthenia and socalled nervousness. According to this report the chest condition cleared up when the prostatitis was relieved. This case suggests a close association between the prostate and thymus, and, if the former gland is in close relation with other members of the endocrine hierarchy, it may be that it is responsible for deviations from health which are at present unassociated with it in theory.

one or two examples from catalogues and criticize the substances contained therein, their relative actions and their doses.

The first example contains thyroid and pituitary substance and a small dose of suprarenal gland. The dose of thyroid in this prescription is a small fraction of a grain. This is obviously wise, as many a physician has found out that the effects of thyroid therapy are widespread, and are likely to be dramatic, more especially in patients much in need of its help. The dose of pituitary (anterior) is even smaller than that of thyroid. I suppose every physician is entitled to form his judgment on matters such as the suitable dose to employ, and this judgment must depend, to some extent, upon his experience and results. I shall not therefore lay myself open to a charge of dogmatizing, if I remark that, in my opinion, a fraction of a grain of pituitary extract (for oral administration) is useless and misleading, as it is too small to produce any results, and the physician therefore concludes that pituitary therapy is not suited to the particular case. Better leave it out altogether, than include it in what is such an obviously inadequate dose, even at the initiation of treatment.

My personal experience has led me to reduce the dose of thyroid substance (except in certain conditions, happily well defined) and to increase that of the pituitary preparations.

While, therefore, in continuing the discussion of this formula, I can find no fault with the dose of thyroid, I should treble the dose of pituitary substance. Personally I have no objection to a basis of nerve tissue.

The inclusion of both thyroid and pituitary substance in the same prescription has a good deal to recommend it, provided the dose of the latter constituent is adequately measured by accepted standards. Both of these substances are stimulators of metabolism, both are active, and both are useful in assisting elimination. I am not convinced, however, that a fraction of a grain of suprarenal gland is going to make or mar the prescription!

The combination of thyroid, pituitary, and an extract of one of the gonads is also a popular formula. Some manufacturing chemists offer a pluriglandular product for the use of males, and another for the use of females; the former having orchitic substance in its composition, and the latter ovarian. On general grounds, and allowing that these substances can be efficacious when taken by the mouth, such a combination can be useful in several types of disorder. As all the components are stimulators of metabolism, they find their *métier* at such times as the climacteric (in both sexes) and might well be selected when premature senility, obesity, in the middle decades of life, or disorders characterized by retention of toxic wastes claim our attention. It may be that the bulk of the work done, and the majority of the benefit which ensues, is due to the thyroid substance. As I have elsewhere stated, I believe that the field for thyroid therapy is ever widening, and that it will continue to widen for many years, as fresh applications of this substance are devised by enterprising physicians.

Its use, and that of many other organotherapeutic preparations, constitutes an attempt, on rational lines, to find shortcuts to normal functions. In many instances, no doubt, therapeutic impatience has outstripped physiological reasoning. And yet, one cannot fail to see that a gigantic new system of treatment has arisen from the minute thyroid grain. A system, moreover, which is rapidly acquiring as wide a range of components as exists in the inorganic pharmacopœia. It is to be hoped, however, that organic polypharmacy will never equal the records held by the inorganic variety!

In the treatment of backward children, many organic preparations have been prescribed. Among these are the thyroid, pituitary (anterior), thymus, pineal, and gonadic extracts. In the mental deficiency which has an underlying hypothyroidism, the exhibition of thyroid extract stands on a firm foundation and is followed by brilliant results. There are also cases in which the signs of hypothyroidism are slight or absent, in which amelioration follows thyroid therapy.

There are, however, many backward patients—and these are of course in the large majority—who do not appear to owe their abnormality to lack of thyroid and who support this belief by deriving no benefit from its exhibition.

With the exception of those children, who owe their mental state to congenital cerebral deficiency, a large proportion of socalled backward children are instances of endocrine dysfunction. They should be helped by a combination of education, environment, and organotherapy.

The glandular substance next in favor to thyroid in this connection is undoubtedly the pars anterior of the pituitary. Let us consider what type of child is likely to benefit from this prescription.

Most clinicians are familiar with the backward, slowwitted child, fat, with poor attentive control and deficient memory. Such children do not, however, always exhibit the physical signs of hypothyroidism, the pulse is not slow, the thyroid gland is palpable, the skin is not harsh and dry—in a word, their mentality resembles the cretin, while their physical signs do not.

It is probable that these children have suffered from thyroid deficiency in their earlier years, that another secretion or secretions has taken on the labors which the thyroid should be performing, and that in time the latter gland has caught up with the growth of the individual, and so, to some extent, the signs of its deficiency are lacking on examination; in other words, it has covered up its tracks.

It comes about, therefore, that an individual such as this may have signs of exhaustion of a gland other than that which has been primarily at fault, because the vicarious deficiency of another secretion has taken undue toll of its resources. Speculation, of course, but the reasoning underlying this is supported by the results of treatment. Furthermore, backward children often rapidly improve at such times as puberty, when fresh internal secretions are thrown into the circulation. Indeed, the characters of many children undergo a complete transformation at such a time as this, and this change must owe its character to the endocrine glands.

Our therapeutic object should be, then, to stimulate those secretions which are responsible for growth, and to do this we may employ, for example, thyroid substance, even though we do not believe the

secretion of this gland to be lacking at the time.

Extract of pars anterior is of great value in the organotherapeutic treatment of delayed development. The records of the help it gives in such cases are good; it is not destroyed in the processes of digestion, and it is well tolerated. Where, as is often the case, there is delayed puberty, the appropriate gonadic substance may with advantage be added to the prescription.

The dose of pituitary substance may be increased to several grains unless there are any contraindications. I have occasionally noted a gastrointestinal disturbance to follow the larger doses of pituitary substance, but this is unusual, and can easily be checked by reducing the dose and subsequently increasing it more gradually. Occasionally a headache follows the exhibition of pituitary substance, but this is not often encountered, and, speaking broadly, this substance is well borne.

The pineal gland requires a brief mention. It is known that this gland is associated with growth and with sexual development. Feeding young animals with pineal substance has been shown to cause acceleration in growth and sexual development. Arguing from the results of these experiments, investigators have administered pineal substance to backward and mentally deficient children. The recorded results are not convincing, but it must be remembered in considering clinical trials of organotherapeutic substances, first, that the preparation may not be active, and, secondly, that the dose administered may be quite inadequate. This was well shown by the earlier experiments in pituitary feeding, where small doses only were given. Later experiments, checked by metabolic tests, showed that relatively enormous doses were required in some cases to produce the changes which, in other cases, had resulted from relatively minute doses.

In spite, therefore, of the absence of good results recorded from a utilization of pineal substance in the treatment of the backward child, it does not follow that, with more extended trials, this preparation will not be shown to be of some use therapeutically. Apparently (to judge from the catalogues) it is being used widely, if in a somewhat haphazard manner, for this class of case. What is required is a series of cases, with controls carefully recorded, and with the results of pineal feeding followed up for some years. It is only in this way that the clinician will be able to satisfy himself that a glandular preparation can do what the manufacturers state for it. It is unsatisfactory to know that feeding an animal with a particular gland produces definite changes in the laboratory, but that the same substance is inert when administered to a human being.

We are at present on the outskirts of a subject possessing vast possibilities, but our advance into its realm must be accompanied by caution. All pioneers have to retrace their footsteps and retract some of their speculations, as further knowledge is obtained. Rash speculation tends only to swamp those facts of which we are in possession; but reasoned deduction from facts capable of proof is a different and legitimate method of procedure.

Organotherapy must be led by endocrinology, for only in this order can sound and lasting results be hoped for in the establishment of a rational method of treatment.

A Case of Exophthalmic Goitre and Diabetes Mellitus*

By J. ARTHUR BUCHANAN, M.D.,
Pueblo, Colorado.

The occurrence of exophthalmic goitre and diabetes mellitus in the same patient presents an interesting problem for therapy. The end result of combined medical and surgical management of the two diseases in certain instances is pleasing.

Case.—The patient, Mrs. A. O. W. (No. 671), aged fifty-two years, first came to the Clinic on November 1, 1921, because of fainting spells; excessive thirst; cessation of menstruation; the passing of large quantities of urine; shortness of breath; generalized weakness, and gradual loss of weight. The symptoms had been present for about six months. She had been troubled with a good deal of pain in the right arm, and occasional mild generalized headaches. The normal weight was 140 to 150 pounds, but at the time of admission she weighed 124½ pounds. The thyroid gland was enlarged. The blood pressure was 150 systolic and 80 diastolic. The pulses were 130 each minute. The radial arteries were palpable. The uterus was completely prolapsed, and a large left inguinal hernia was found.

*From the Section in Medicine, Pueblo Clinic.

The subsequent course of this patient is given in the clinical notes in combination with the laboratory findings. The twenty-four hour urinary output is reported in each instance, unless otherwise stated. Where sugar and albumen are absent the report is not included.

11/3/21—Urine, 4,000 c. c.; sp. g., 1.027; albumen, faint trace; sugar, 160 grams.

11/8/21—Urine, 3,500 c. c.; sp. g., 1.037; albumen, faint trace; sugar, 145.95 grams.

11/11/21—Blood sugar, 452 mgs. for each 100 c. c. of blood. Wassermann on blood serum reported as four plus.

11/14/21—Restricted diet, but food not weighed. Sugar tolerance not determined.

11/17/21—Urine, 2,000 c. c.; sp. g., 1.018; albumen, faint trace.

11/22/21—Urine, 2,000 c. c.; sp. g., 1.014; albumen, faint trace.

11/25/21—Complaining of inability to see properly. Nothing abnormal in eyes.

11/29/21—Urine, 2,000 c. c.; sp. g., 1.016; albumen, faint trace.

12/1/21—Had diarrhea.

12/13/21—Urine, 1,500 c. c.; sp. g., 1.015.

12/15/21—Has been having paroxysms of severe pain in lower left abdomen. The attacks last for a few hours. Pulses, 100 each minute; blood pressure, 140 systolic and 84 diastolic; weight, 126 pounds.

12/27/21—Urine, 2,000 c. c.; sp. g., 1.010.

12/29/21—Weight, 124 pounds (56.3 kg.). Had an attack of pain, left side of lower abdomen, lasting about six hours. Says it is difficult to urinate during these attacks.

1/3/22—Urine, 2,000 c. c.; sp. g., 1.024.

1/5/22—Had a slight cold in nose.

1/17/22—Urine, 1,500 c. c.; sp. g., 1.030; albumen, very faint trace; sugar, 31.5 grams.

1/24/22—Urine, 1,500 c. c.; sp. g., 1.025.

1/31/22—Urine, 2,000 c. c.; sp. g., 1.035; sugar, 67 grams.

2/9/22—Urine, 2,000 c. c.; sp. g., 1.025; sugar, 50 grams.

2/16/22—Urine, 2,000 c. c.; sp. g., 1.026; sugar, 32 grams.

2/23/22—Urine, 2,000 c. c.; sp. g., 1.025; sugar, 25 grams.

3/2/22—Urine, 2,500 c. c.; sp. g., 1.027; albumen, very faint trace; sugar, 50 grams.

3/7/22—Fullness in head; blood pressure, 160 systolic and 90 diastolic.

3/9/22—Urine, 2,500 c. c.; sp. g., 1.025; albumen, very faint trace; sugar, 200 grams.

3/12/22—Sugar in urine. Patient had finished a course of antiluetic treatment, and believed that to be the cause of the sugar flareup, but study of the diet insrtuctions showed diet to be the cause.

3/14/22—Urine, 2,000 c. c.; sp. g., 1.012.

3/22/22—Urine, passed specimen; sp. g., 1.017; sugar present.

4/5/22—Urine, passed specimen; sp. g., 1.030; albumen, very faint trace; sugar present.

4/10/22—Is feeling well; weight, 126 and one quarter pounds.

4/11/22—Wassermann on blood serum reported as four plus.

4/18/22—Urine, 1,500 c. c.; sp. g., 1.025; albumen, very faint, trace; sugar, 45 grams.

5/2/22—Urine, 1,500 c. c.; sp. g., 1.028; albumen, very faint trace; sugar, 6.5 grams.

5/23/22—Urine, 2,000 c. c.; sp. g., 1.039; albumen, very faint trace; sugar, 50 grams.

5/25/22—Has been feeling quite well except for hay fever. Weight, 129 and one half pounds; blood pressure, 165 systolic and 94 diastolic.

6/14/22—Urine, 2,000 c. c.; sp. g., 1.023; sugar, 31.2 grams.

8/22/22—Urine, passed specimen; sp. g., 1.021; albumen, very faint trace; sugar present.

8/25/22—Pulses, 120 each minute; blood pressure, 140 systolic and 85 diastolic; weight, 122 pounds; feeling weak.

8/30/22—Urine, 3,000 c. c.; sp. g., 1.029; albumen, very faint trace; sugar, 135 grams.

8/31/22—Pulses, 102 each minute, and irregular; weight, 125 pounds; feeling better.

9/13/22—Urine, 3,000 c. c.;; sp. g., 1.025; sugar, 93.6 grams.

9/15/22—Physical exam.: Blood pressure, 160 systolic and 90 diastolic; pulses, 120 each minute; looks very warm; sweating freely; nervous; finger nails linear corrugation, plus two; brittle, plus one; turned up, plus one; static tremor of fingers present; face flushed; eyes stary; right quadriceps strength, minus two; left, minus one to two; thyroid, smooth, hard enlargement; left lobe, two x one and one quarter in.; right lobe not felt; no nodules; no bruits nor thrills; tongue red; edema of left leg, minus one; stripped weight, 119 pounds; height, sixty-one and one quarter in.; age, fifty-three years; total calory requirement, 1,293. The patient was put on thirty-six grams of protein, 110 grams of fat and seventeen grams of carbohydrate. The diet had to be weighed and measured accurately.

9/19/22—Urine, 2,000 c. c.; sp. g., 1.012; acetone and acetoacetic acid present; weight, 118 and one half pounds.

9/20/22—Basal metabolic rate, plus 55. Increased diet by ten grams of protein, eighteen grams of fat, and forty grams of carbohydrate.

9/22/22—Has been having pain in left abdomen; now profuse diarrhea; vomited for two days; marked odor of acetone on breath; pulses, 132 each minute.

9/24/22—Pulses, 102 each minute; no diarrhea; acetone gone from breath.

9/25/22—Urine, 2,000 c. c.; sp. g., 1.038; sugar present; acetone and acetoacetic, none.

9/27/22—Urine, 2,500 c. c.; sp. g., 1.015; sugar, 10.5 grams; pulses, 114 each minute; weight, 119 pounds; feels well; diet reduced by four grams of protein and twenty grams of carbohydrate.

9/29/22—Urine, 3,000 c. c.; sp. g., 1.022; had diarrhea today; weight, 116 and one half pounds; pulses, 120 each minute; sweating and very warm.

10/1/22—Acetone and acetoacetic acid present in urine. Patient sent to hospital to prepare for thyroidectomy.

10/5/22—Acetone and acetoacetic acid still present, but generally improved; pulses less rapid; weight, 113 pounds; basal metabolic rate, plus fifty-two.

10/6/22—In bed in hospital one week; still running acetone and acetoacetic acid; pulses better; strong odor of acetone on breath.

10/8/22—Pulses slower; general appearance improved.

10/12/22—Acetone, faint trace.

10/13/22—Acetone still in urine; less nervous; pulses slower; blood sugar, 115 mgs. each 100 c. c. of blood.

10/14/22—Urine, 2,000 c. c.; sp. g., 1.022.

10/15/22—Urine, acetone and acetoacetic acid free; put on list for operation; surgical risk estimated as three on basis of four.

10/16/22—Partial thyroidectomy under ether anesthesia by Dr. Black; pulses very rapid after operation; acetone and acetoacetic acid present in urine in the evening.

10/17/22—Refused nourishment; general condition good.

10/18/22—Had desire for food; pulses, 160 each minute; acetone and acetoacetic acid not found in urine.

10/20/22—Pulses, 140 each minute; skin warm, but no sweating; appetite was normal.

10/21/22—More comfortable; things do not bother as they used to; not so warm; can keep bed clothes on now, something she has been unable to do for over a year; pulses, 110 each minute; pathological report: Hypertrophy and hyperplasia—exophthalmic goitre.

10/26/22—Postoperative course has been very uneventful; weight, 108 pounds; pulses, 90 each minute; basal metabolic rate, plus five.

11/2/22—Urine, 2,500 c. c.; sp. g., 1.022.

11/3/22—Pulses, seventy-eight each minute; calm; no sweating; feels "so different"; has to use more covers at night; appetite is unusually keen; sleeps soundly all night; increased diet by twenty-eight grams of carbohydrate, nine grams of protein and sixteen grams of fat.

11/11/22—Urine, 3,500 c. c.; sp. g., 1.016; albumen, faint trace.

11/20/22—Weight, 113¾ pounds; pulses, ninety each minute; has noticed some edema of the legs in evening; looks well; feeling stronger; strength of thigh muscles improving.

11/27/22—Urine, 3,500 c. c.; sp. g., 1.020; albumen, very faint trace; weight, 115 and one quarter pounds; pulses, ninety each minute; still slight edema of legs; appetite not excessive; feels very well; blood pressure, 190 systolic and 110 diastolic.

12/18/22—Urine, 3,000 c. c.; sp. g., 1.025; albumen, faint trace; acetone present; has had more or less headache for the last week; no fever; ached all over body; eyes feel weak; morning headache; weight, 121½ pounds; pulses, eighty-four to ninety each minute; blood pressure, 178 systolic and 100 diastolic.

12/26/22—Bowels have not moved; vomited; some sense of soreness in abdomen; strangulated left inguinal hernia; passing gas, but not so much today as before; some distention; active peristalsis; tenderness plus one over lower abdomen; on admission to Parkview Hospital, face flushed, skin red, elbows red, and complaining of intense itching of whole body. Reduction of hernia under local anesthesia. Bowel was quite dark, but color gradually returned.

12/27/22—Urine, passed specimen; sp. g., 1.018; albumen, four plus; sugar present; hyaline granular and epithelial casts, twenty to each microscopic field; patient moaned constantly most of the night; expelled a great deal of flatus; abdomen distended; no appetite; nauseated most of the time.

12/28/22—Projectile vomiting; complaining of pain in the abdomen, which is distended, but soft; belches frequently; during the night vomited a thick brown fluid with fecal odor.

12/29/22—Vomited frequently; restless and moaning frequently; expelling considerable flatus; during afternoon rested well.

12/30/22—Slightly bloody discharge from wound; ex-

pelling gas frequently; fair results from high medicated enema.

12/31/22—Small constipated stool; drinking large quantities of water; no nausea nor vomiting; slightly bloody discharge from wound.

1/1/23—Restless; large semiformed stool; more drainage from incision.

1/2/23—Fecal drainage from wound.

1/3/23—Generally feeling well; drainage from wound decreased.

1/4/23—Generally improving, but has a large fecal fistula.

1/6/23—Urine, 1.687 c. c.; sp. g., 1.010; albumen, faint trace.

1/10/23—Had an attack of abdominal pain with diarrhea; looks well; skin peeling from hands and arms.

1/14/23—Feeling better; little drainage from wound now; skin has desquamated in large and small scales from whole body.

1/19/23—No drainage for three days.

1/22/23—Urine, 2,500 c. c.; sp. g., 1.016; albumen, faint trace.

1/23/23—Increased diet by 12.5 grams of carbohydrate, 16.5 grams of protein and twelve grams of fat.

2/2/23—Looks well; passes large quantity of urine one day and less the next.

2/17/23—Weight, 122½ pounds; blood pressure, 180 systolic and ninety-five diastolic; pulses, ninety-six each minute; has some swelling of the legs at times; complaining of slight pains in legs and arms; urine was sugar free; diet is sufficient to satisfy appetite.

3/29/23—Weight, 131¼ pounds; blood pressure, 180 systolic and ninety diastolic; pulses, eighty-four each minute; says legs swell, but general strength greater than for years; satisfied with diet; blood sugar, 187 mgs. each 100 c. c. of blood.

4/13/23—Weight 137 pounds; patient is the picture of health; no increased appetite; feet swell in afternoon; pulses, ninety-six each minute; no dyspnea on exertion.

5/13/23—Weight, 142½ pounds; blood pressure, 190 systolic and 110 diastolic; pulses, ninety each minute; has no complaints; appetite is normal.

6/2/23—Weight, 142 pounds; had been having pain just to the left of the umbilicus; there were no objective signs.

7/14/23—Weight, 150¼ pounds; had hay fever; no swelling of the feet; pulses, ninety-six each minute; still has some pain over the left side of the abdomen; bowels regular; blood pressure 180 systolic and 100 diastolic.

COMMENT.

For several years there has been discussion concerning the relation of the thyroid gland to diabetes mellitus. The literature on this subject has been summarized by Fitz (1), who, at the same time, briefly reported the results of surgical treatment of hyperthyroidism when complicated by diabetes mellitus. The series was small, but from the end results he felt that it did not seem overradical to advise operation for properly selected and prepared patients, since the risk does not seem out of proportion to the possible benefit to be gained, and since the prognosis is otherwise grave.

The medical management of exophthalmic goitre and diabetes mellitus are so diametrically opposite that success could hardly, if ever, be realized. The patient with the former disease must be overfed in order to maintain body weight and strength, whereas the patient with diabetes mellitus must live on a restricted diet. The problem in a patient with the two diseases is almost impossible of solution to the advantage of the patient without the eradication of one of the two diseases. Diabetes mellitus cannot be eradicated. At present the most satisfactory method of reducing the hyperthyroidism appears to be by surgical measures. The introduction of insulin will help to minimize the surgical risk in these patients.

The data in table 1 show the steady improvement

TABLE 1.

SHOWING STEADY INCREASE IN CARBOHYDRATE TOLERANCE AFTER THYROIDECTOMY.

Grams of Carbohydrates.	Grams of Protein	Grams of Fat.
17	36	110—Basic diet, 9/15/23
28	13	5—Increased, 9/20/23
45	49	115—Urine contained 10.5 grams sugar
20	4	—Reduction, 9/27/23
25	45	115—Total food tolerance before thyroidectomy
28	9	16—Increase eighteen days after thyroidectomy
12.5	16.5	12—Increase, 1/23/23
65	70	143—Present diet, on which urine is sugar free and patient has normal appetite.

TABLE 2.

SHOWING IN KILOGRAMS THE WEIGHT CHANGES BEFORE AND AFTER THYROIDECTOMY.

Before Thyroidectomy		*After Thyroidectomy*	
Date		*Date*	
Normal	63.6	Normal	63.6
11/1/21	56.5	10/26/22	49.0
12/15/21	57.2	11/20/22	51.7
12/29/21	56.7	12/18/22	55.2
4/10/22	57.3	2/17/23	55.6
5/25/22	58.8	3/19/23	59.6
8/25/22	55.4	4/13/23	62.2
8/31/22	57.0	5/13/23	64.7
8/15/22	54.0	6/2/23	64.7
9/19/22	53.8	7/14/23	68.2
9/29/22	52.9		
10/5/22	51.3		

that has occurred in the carbohydrate tolerance of the patient, while table 2 shows weight changes. There may be a relation between the thyroid and the pancreas in diabetes mellitus, or there may not be. The improvement in the general nutrition of the patient may be due entirely to a return to a normal rate of tissue loss and repair. The increase of carbohydrate tolerance probably indicates a greater endogenous production of insulin or better utilization of the normal output, or both. The patient now diets to keep from gaining more weight as well as to keep her diabetes under control.

The value of weighing the food, in caring for patients with diabetes, is shown in this patient, as sugar has not appeared in the urine while following this regime. The co-operation on the part of the patient has always been entirely satisfactory. The operation for intestinal obstruction would have been hazardous in an improperly controlled diabetic, and still more so if the hyperthyroidism of exophthalmic goitre were present.

The presence of syphilis does not appear to affect this patient's life in any way. There are no organic signs of syphilis, and in view of that fact, no further antiluetic treatment has been advised, even in the face of repeated four plus Wassermann reactions.

The end result in this instance by breaking one link in the association of the two diseases in the same patient is such as to stimulate a repetition of the same procedure under similar circumstances. The earlier the hyperthyroidism is eradicated, the greater the chances of success.

Goitre Hearts

By S. STRICKLAND GOODALL, M.B., M.R. C.P., M.S.A. Lond., F.R.C.S., F.R.S. Edin.,
London,
Senior Physician to Out Patients, National Heart Hospital, London; Late Lecturer on Physiology and Sub-Dean Middlesex Hospital,

At the present time when surgeons, physicians, anesthetists, radiologists, and even psychotherapeutists are interesting themselves in goitres and their treatment, the following brief remarks on the condition of the heart in goitre may be neither out of place nor inopportune. The association between disease of the thyroid and the heart has been long known and has been commented upon especially by German writers. The following remarks are based on personal observations made in several hundred cases, the majority having been referred to me by James Berry or C. A. Joll for cardioanalysis prior to operation.

Roughly speaking goitre hearts fall typically into two main groups, 1, pneumomechanical; 2, thyrotoxic.

PNEUMOMECHANICAL HEARTS.

Pneumomechanical hearts occur typically in those cases where, owing to thyroid enlargement, there is definite pressure on the vessels and nerves in the neck, together usually with a varying degree of obstructive dyspnea due to pressure on the trachea. Pressure on the veins leads to obstructed venous return, small input, and consequently small output with rapid heart action.

The forced inspiratory efforts mean increased suction action and the heart ultimately becomes fatigued and atonic and so enlarged. X ray examination usually shows a rapid, rather large, somewhat horizontal heart, resting on the diaphragm. Such hearts are most common in cystic adenomata, but may occur in other thyroid enlargements. Electrocardiographic examination shows a physiological tachycardia, but the P (auricular) waves are not unduly increased in amplitude and do not generally equal the T (ventricular) waves.

A right sided preponderance is not infrequently present. The peripheral vessels are constricted, so that in spite of the small output, the blood pressure is usually high.

These hearts, although rapid and somewhat enlarged, in uncomplicated cases are neither poisoned nor degenerated and hence rapidly recover after operation.

THYROTOXIC HEARTS.

Thyrotoxic hearts are seen in cases of hyperthyroidism, and especially in Graves's disease (1). They are rapid—120 or more—while the beat is augmented. The input is not interfered with and the peripheral resistance is usually relaxed and the blood pressure low, due to vasodilatation, caused by a depressor substance which has been isolated from the gland in these cases. Hence the flushed, warm, moist skin and increased susceptibility to heat so well known in hyperthyroidism.

Myocardial fatigue, atonia, valve incompetence with actual dilatation, toxemia and myocardial degeneration may all result if the case continues for any length of time. On x ray examination the heart appears typically rather large and horizontal, the apex often being outside the nipple line, while electrocardiographic examination shows all grades of curve from a simple physiological tachycardia in recent cases, to definite myocardial degeneration, indicated by an increased PR interval (= diminished conductivity of auriculoventricular bundle), auricular fibrillation, or some other marked abnormality in the form of complexes.

These hearts differ from the pneumomechanical hearts, chiefly in that they are poisoned and degenerated as well as fatigued, and hence not only add materially to the risk of an operation, but take a considerable time to recover after an operation.

A primary pneumomechanical heart may present thyrotoxic signs, and either a pneumomechanical or thyrotoxic condition may be engrafted on a heart which has previously been damaged by some antecedent disease such as rheumatic fever, when the risk assessment for operation becomes extremely difficult.

The main features of the pneumomechanical and thyrotoxic hearts and their associated circulatory conditions may be summarized as follows:

PNEUMOMECHANICAL.	THYROTOXIC.
A. *Heart.*	A. *Heart.*
1. Rapid, but usually below 120.	1. Rapid, usually 120 or above.
2. Beat not augmented.	2. Beat augmented.
3. Small in size and only enlarged later.	3. Usually enlarged.
4. Input small.	4. Input normal.
B. *Myocardium.*	B. *Myocardium.*
1. Usually slightly exhausted.	1. Usually definitely exhausted.
2. Atonia slight.	2. Atonia usually marked.
3. Dilatation slight or absent.	3. Dilatation very often present
4. Degeneration usually absent.	4. Degeneration often present.
5. Valve incompetence not very common.	5. Valve incompetence usually present.
C. *Pericardium.*	C. *Pericardium.*
1. Basal rub not very common.	1. Basal rub present in over fifty per cent. of cases.
D. *Electrocardiogram.*	D. *Electrocardiogram.*
1. Rightsided preponderance not uncommon.	1. Leftsided preponderance not uncommon.
2. PR interval usually normal (below one fifth seconds).	2. PR interval often one fifth or above.
3. P waves usually less in amplitude than T waves.	3. P waves usually=T waves in amplitude.
4. Auricular fibrillation rare.	4. Auricular fibrillation common (twenty per cent.)

ASSOCIATED PERIPHERAL CONDITIONS.

PNEUMOMECHANICAL.	THYROTOXIC.
1. Peripheral vessels not relaxed.	1. Peripheral vessels markedly relaxed.
2. Venous tone relatively high.	2. Venous tone relatively normal.
3. Capillary pulse absent.	3. Capillary pulse often present.
4. Arterial blood pressure normal or raised.	4. Arterial blood pressure triphasic, usually low (ten to twenty per cent.)
5. Digitalis slows rate and increases tone.	5. Digitalis does not slow but increases tone.

AURICULAR FIBRILLATION.

Auricular fibrillation is of such special interest in thyroid cases that the following additional notes may be of interest:

Normally the auricular muscle fibres contract in an orderly coordinate manner, the contraction commencing in the region of the sinoauricular node and spreading down toward the ventricle. In auricular fibrillation this coordinate contraction does not occur, the different bands of muscle contracting irregularly and more or less independently. The degree to which this dissociation and ineoordination has occurred determines whether the resulting fibrillation is of the socalled coarse or fine variety. In my own series of cases, fifteen per cent. showed auricular fibrillation, ten per cent. exhibiting the condition before, and five per cent. developing it after operation. Generally speaking, the condition develops after the disease has been in progress for some years, and must be regarded as indicative of the fact that the myocardium is profoundly poisoned or that degeneration has definitely commenced. Occasionally Graves's disease starts with auricular fibrillation, and in these cases the condition usually persists. Not infrequently (about five per cent.) auricular fibrillation develops during or soon after operation on the thyroid and may occur after any operation from simple ligation to extirpations of varying extent. Usually the condition is only temporary. Its onset is often synchronous with a rise in blood pressure (2).

On the other hand, cases of Graves's disease which show auricular fibrillation and may in some cases have exhibited it for years, frequently cease fibrillation after removal of part of the thyroid, especially if treated by quinidine, which appears, in many cases at any rate, to influence materially such cases after a partial thyroidectomy. It is in those cases where the auricular fibrillation depends upon a toxic, and not upon a degenerative condition, of the myocardium, that recovery occurs.

In conclusion, one would once more emphasize the facts that in the case of the pneumomechanical heart the operative risk is comparatively slight, although the patient may be in desperate straits from obstructive dyspnea because the heart, although exhausted, is not poisoned or degenerated. On the other hand, in the case of the thyrotoxic heart, the risk is comparatively high, because the heart is not only exhausted but poisoned and degenerated as well. Furthermore, as regards postoperative recovery, in the former cases it is rapid and frequently incomplete, in the latter, always slow and frequently incomplete.

Finally, one might mention that the most complex and difficult of all cardiac cases to assess in connection with goitre, are those in which the subject early in life manifested some condition such as rheumatic fever, resulting in definite cardiac damage. Such a subject later in life develops a cystic adenoma with marked thyroid enlargement, when pneumomechanical signs are superimposed on the old rheumatic heart. Later the goitre may become toxic when thyrotoxic signs are further superimposed. In such cases as these it is almost impossible to determine how much of the damage is rheumatic and how much thyroid in origin.

The Endocrine Glands and Immunity

By MAURICE UZAN, M.D.,
Paris, France.

Notwithstanding the marked advances made since Pasteur by such men as Chauveau, Metchnikoff, Behring, Pfeiffer, and Bordet—to mention only the foremost—the exact nature of the phenomena of immunity has remained obscure. Again, since Claude Bernard and Brown-Séquard, another mysterious phenomenon, that of the internal secretions, has awakened interest among scientific men and become the subject of most fruitful investigations. Correlation between these two lines of research must necessarily at some time have taken place, and was not long delayed, as the event proved.

Even in Brown-Séquard's time it was generally conceived that the internal secretions had for their purpose to neutralize certain toxic substances normally produced in the tissues. But this conception was soon left far behind and attempts were made to attach to the ductless glands likewise a defensive function against substances foreign to the organism. The ductless glands thus became the essential supports of Grasset's *antixenism,* of Sajous's original and ingenious theory, and of various hypotheses.

It is now an opportune time to review this question from the point of view of recent data, and to ascertain what conclusions experimental work supports and what new lines of research are opened by it to investigators.

Such is the purpose of the present article. I have already published elsewhere a very extensive study of the subject; this will make it unnecessary to append hereto tedious bibliography to which, however, the reader may easily refer if he so desires (1).

The first fact to arrest the attention of observers is the frequency of involvement of the ductless glands during infections and intoxications. The thyroid, adrenals, hypophysis, ovary, and testicle are often diseased in the course of a great variety of toxic infectious states, such as tuberculosis, syphilis, typhoid fever, influenza, scarlet fever, smallpox, diphtheria, mumps, acute rheumatism, infections of the digestive tract or lungs, streptococcic infections, cholera, tetanus, meningococcic disorders, malaria, and other infections; in the presence of exogenous

intoxications by lead, mercury, alcohol, chloroform, and other substances, and in autointoxications, including in particular those due to pregnancy.

Roger and Garnier, Torri, and Crispino, in connection with the thyroid; Charrin and Langlois, Oppenheim and Loeper, and Polak and Mulon, in connection with the adrenals; Garnier and Thaon, and Rénon and Delille, in connection with the hypophysis, and Ancel and Bouin, in connection with the sex glands, have been the authors of investigations along these lines. Some merely recorded the observed facts, while others interpreted these facts as evidences of the antitoxic rôle of the ductless glands. As a matter of fact, such interpretations were not wholly justified by the observations made.

Many different organs may be involved, indeed, in a wide variety of toxic infectious states; yet this fact has never been considered ground for ascribing an antitoxic function to these organs. Furthermore, the pathological lesions most often found are destructive lesions such as hemorrhage, suppuration, degeneration, and fibrosis, and it is hard to see how finding a destructive lesion in an organ constitutes proof of an antitoxic function on the part of that organ. In some instances, however, experimenters have actually found hypertrophic conditions or evidences of increased glandular activity which were more in keeping with their interpretations. In the case of the adrenals, in particular, Langlois and Charrin, and Mulon and Porak have reported many instances of this kind. That the glandular hypertrophy observed leads to overproduction of a normal secretion remains, however, to be demonstrated. Garnier found in cases of experimental hypertrophy of the thyroid that the colloid material, while present in enormous excess, no longer had the usual staining reactions. Again, why should not the possibility be recognized that this glandular hypertrophy is merely the expression of a local defensive process (protection of the gland itself), as was suggested by Voinov when he analyzed the experiments of Ancel and Bouin on the testicles?

To get around this difficulty some observers have sought to determine the amount of secretory products in the gland itself. Thus, Giraud, and Labbé and Vitry have made determinations of the amount of iodine in the thyroid, and Lucksch, Tedeschi, Rossi, and others, of the amount of adrenalin in the adrenals. In this connection it would be necessary to know, in the first place, whether the secretion is always of the same kind; in the case of the adrenals in particular, it is well known that in addition to adrenalin, these glands secrete lipoids, the rôle of which in infectious diseases has been shown by the researches of Chauffard. Further, it has been demonstrated that one cannot form an estimate of the secretion of the adrenals on the basis of the reserve of adrenalin contained in these glands (Stewart and Rogoff, Gibson, Kuriyama).

Other authors have thought they were getting nearer to the truth by studying the output of glandular secretions into the efferent veins. Tchebocsaroff, in particular, asserts that he noted a reduction of the adrenalin in the blood of the adrenal veins from the second to the sixth day of experimental diphtheria. Here again, however, it is hard to form an exact idea, as little is known about the actual secretions of the adrenal and the unity of such secretions has not been demonstrated.

Yet it has appeared feasible to certain investigators to recognize such glandular hypersecretion in the blood stream, either by methods demonstrating directly the secretory excess (dialysis method) or by procedures showing the resistance of the organism at large to the excessive functioning (complement fixation method). The Abderhalden reaction was utilized in this connection. Dietrich's reaction is the reaction of complement fixation as applied to thyroid hypersecretion. It is asserted to be positive in the presence of fever. Both of these reactions when actually applied, however, yielded most conflicting and unexpected results, and must be rejected as unsuitable, at least in the form in which they are now in use.

A few observers then thought that if the ductless glands had an antitoxic function, extracts of these glands might neutralize toxines *in vitro* and possess bacteriolytic properties. Thus, it was shown that the vitality of germs was reduced when they were grown on such glandular media as thymus (Brieger, Kitasato and Wassermann), thyroid, suprarenal, testicle and ovary (Parhon and Savini). Turri has recently shown, however, that all tissue extracts possess more or less bacteriolytic activity on account of the ferments common to all cellular elements, and that the action of fat solvents and probably also that of substances favoring the saturation of fatty acids enhances the solubility of these ferments in saline solution, and that consequently the bacteriolytic property referred to is supported by fatty substances or lipoids —a view already expressed by Landsteiner and Ehrlich. It has also been shown that these gland extracts are able to neutralize bacterial toxines (Remedi, A. Marie) or other toxic substances (Langlois and Charrin, Abelous, and Oppenheim, in the case of the adrenals). It seems possible, however, that this neutralizing action may always be due to these lipoids or fats, and one should bear in mind the splendid experiments carried out in Delezenne's laboratory on the neutralization of snake venoms by lipoids.

It has also seemed justifiable to think that these gland extracts might possess an antitoxic action, or at least one of stimulation of the processes of defence, *in vivo*. Thus, it was observed that ingestion of thyroid extract was capable of increasing the amount of complement in the blood serum (Miss Fassin, Bruns), phagocytic power (Marbé), the opsonic index (Marbé, Stépanoff), hemolytic power (Yustchenko, Koopman), leucocytosis (Donzello and Venuti), and the property of agglutination (Borchardt). Administration of adrenalin has been held to increase the agglutinating power (Borchardt) and to enhance the tuberculin skin test (Bouveyron). Pituitary extract has been held to increase the complemental power of the serum (Donzello and Venuti). Yet, Farrant admits that injection of extracts of thyroid colloid fails to save guineapigs poisoned with diphtheria toxin. Parhon and Mme. Parhon observed that fowls rendered hyperthyroid were less resistant to cholera than normal fowls. Strubell and Michligk found the opsonic index lowered in guineapigs to which thyroid was administered. Couland has observed that thyroid opotherapy exerts an unfavorable influence on the course of tuberculous

disease and inhibits the tuberculin skin test. Bijlisma, in contradiction to Borchardt, did not find the agglutinating power affected after administration of adrenalin. Conflicting results are not the only objectionable feature of the experiments described above. The products of internal secretion not having as yet been isolated, the gland extracts used contain, in addition, proteins and lipoids, the action of which may itself suffice to account for the experimental results obtained. Thus, it is known that proteins alone may increase the complement of the serum (Bordet, Nolf) and likewise the agglutinins (Kirstein); lipoids are capable of yielding like results, as mentioned in a recent contribution by Linossier.

Experiments consisting of the removal of the ductless glands have been more illuminating. After removal of the thyroid, there have been noted reduction of the complement content of the serum (Miss Fassin, Muller, Marbé), of the opsonic index (Palazzo, Marbé), of the hemolytic property of the serum (Carlson), of the production of diphtheria antitoxin (Houssay), and of the resisting powers to tuberculous infection (Miss Bernard), to a great variety of poisons, such as sodium arsenite, mercury bichloride (Jeandelize and Perrin), caffeine (Lindeman), and cocaine (Sanchis Banus), as well as to uremic intoxication (Rémond and Minvielle), etc. After adrenalectomy the experimental subjects have shown less resistance to various toxics, such as neurine (Albanese) and atropine (Langlois, Abelous, Boinet), and to various infections or intoxications (Langlois and Charrin, Oppenheim and Loeper, Camus and Porak, J. T. Lewis), including that by diphtheria toxin (A. Marie). Castration is asserted to cause a lowering of the opsonic activity of the blood and to reduce the power of defence against infection (Candro and Torelli, Marchesi, Metchnikoff).

In contrast with these findings, however, several observers have noticed that thyroidectomy not only did not reduce the defensive powers, as reported by Bianchi Manotti already in 1895 and later by Diez and Lerda, Frouin, Fjelstadt, Launoy and Bruhl, Hektoen and Curtis, and others, but could even act favorably on the phenomena of immunity (Garnier, Marañon, Garibaldi, J. Clevers). As regards the adrenals, Giusti, Bijlisma, and others do not believe that removal of these glands is capable of exerting an unfavorable effect on the processes of immunity.

These contradictions are readily accounted for if one will recollect the difficulties attending the performance of such operations—operative shock, injury to adjacent organs, and others—as well as the untoward consequences resulting from such removal in animals owing to the disturbances of nutrition occasioned; as a result of this, the actual fact is that one is generally experimenting on moribund animals.

Thus, up to the present time, all the methods of study herein reviewed are inadequate to clear up the problem under discussion. There are two methods, however, which, in my estimation, might, if properly applied, throw some light on the subject, and are deserving of further trial.

The first of these comprises the experiments consisting of the intraglandular injection of toxic substances or of bacteria. The artificial circulation experiments already attempted by many observers in relation to the liver and by Roger in relation to the lungs with a view to demonstrating the inhibitory action of these organs on germs or poisons, might be applied to the other ductless glands. Few experiments of this kind have been carried out, and the occasional attempts known to the writer concerned only the thyroid gland. As a matter of fact, they yielded conflicting results. Franceschi found the mortality among the experimental animals increased when he introduced diphtheria toxin, not in the general circulation, but in the thyroid artery. Remedi, on the other hand, found that injections of killed cultures of anthrax, diphtheria, or tetanus germs were less virulent in the thyroid than under the skin. Between these two extremes, the experiments of Diez and Lerda, and especially of Bassinger, failed to reveal any difference between the results following injection of toxic substances into the thyroid and those following subcutaneous injection.

These investigations should be repeated. Injections into the parenchyma should be discarded as causing too much trauma. The toxic material should be introduced slowly and in an aseptic manner preferably in isotonic solution through the afferent artery to the organ under investigation. It will then be necessary to ascertain:

1. Whether the lethal toxic dose injected into the afferent artery is greater than the lethal toxic dose injected subcutaneously in control animals.

2. The changes relating to immunity reactions: Complement, agglutinins, precipitins, etc.

3. The content of toxic products in the blood of the efferent vein.

4. The histological and histochemical reactions awakened in the gland by the product under investigation.

The second method does not seem to have been used as yet, at least not to the writer's knowledge. Nevertheless, it would appear to be of marked interest. If it is actually true that the endocrine glands take part in the production of immunity, or more precisely, of the antibodies associated with such immunity, the blood contained in these glands, or at least the blood issuing from them, should contain more of the antibodies than blood from other portions of the body. In consequence, it would be appropriate to ascertain exactly the distribution of the antibodies in the blood, including particularly the relative amount in the blood of the efferent veins of the ductless glands.

The foregoing represents the present state of the question which I have taken the liberty of discussing in this paper. Many experiments have been performed; yet very few of them are really conclusive and immune to all criticism. Much effort, laudable but disconnected, has been expended. No comprehensive work on the subject has been conducted experimentally. The purpose should now be, after having subjected all that has been done so far to due criticism, to formulate a new plan of work. The brief study herein presented does not pretend to be anything more than an introduction to this work. If it shall merely lead a few investigators to experiment further on the question its purpose will have been amply fulfilled.

Analysis of Fifty-two Goitre Cases, with Discussion of Treatment Employed in Different Types*

By J. WILLIAM HINTON, M.D.,
New York,
Associate in Surgery at the New York Post-Graduate Medical School and Hospital.

This paper is based on the observation of fifty-two goitre cases treated in the Outpatient Department of the New York Post-Graduate Medical School and Hospital during the past two and a half years, ending with 1922.

First, I will give the classification that has been employed in this clinic.[1]

1. Goitres with approximately normal secretory activity or hypothyroidism. a. Simple and endemic goitre. Pathological gland with secretory activity diminished. b. Goitres with adenoma. Pathological gland with secretory activity diminished or normal. c. Colloid goitre. Pathological gland with secretory activity diminished.

2. Goitres with increased secretory activity. a. Adolescent goitre. Physiological gland with slightly increased secretory overfunction. b. Goitre with adenoma. Pathological gland with overfunction. c. Goitre of Graves's disease. Pathological gland with overfunction of dysfunction.

3. Goitres with degeneration. a. Malignant goitres. Pathological gland with variable secretory activity. b. Goitres with cystic, hemorrhagic, fibroid or hyaline degeneration. Pathological gland with diminished secretory activity.

I.—GOITRES WITH APPROXIMATELY NORMAL SECRETORY ACTIVITY OR WITH HYPOTHYROIDISM—ADOLESCENT GOITRE.

This series included sixteen adolescent goitres. The average age was 15.2 years, the oldest patient being nineteen, the youngest twelve years old. All were females. The average duration of the disease was 2.95 years; the longest duration eleven years; the shortest four weeks. Basal metabolism determinations were done on all of these cases, with twenty-seven per cent. showing a normal reading, thirty-three per cent. showing decreased metabolism, and forty per cent. increased metabolism. The average decrease was minus 10.5 per cent.; the average increase, plus eleven per cent.

Of these cases one was referred for admission but did not enter the hospital. The patient, H. H., aged nineteen, first noticed swelling eleven years ago. Did not improve with thyroid extract, one grain t. i. d. The basal metabolism was plus six at the first determination. Two months later it was minus one. After being under observation for five months and continuing to enlarge, the patient was referred for admission due to pressure symptoms.

This type of goitre is seen in young women at or before the age of puberty. These patients give a history of the mother having had thyroid trouble. They are usually among the poorer classes who have begun work early in life and are poorly nourished, anemic, and have foci of infection—tonsils, teeth or sinuses. The diagnosis of this condition is usually easy. There is a symmetrical enlargement of the thyroid in a girl at or about the age of puberty, which is rather soft and does not give a definite thrill on palpation. The patients also give a history of the growth enlarging during the menstrual periods.

The treatment of this condition is medical, beginning with the eradication of any focus of infection, correcting faulty hygiene, advising open air life as much as possible and the keeping of regular hours. Metabolism readings should be ordered in all cases when first seen. It is an iodine deficiency disease and iodine has to be supplied. This may be given in the form of thyroid extract, one grain, ovarian substance, three grains, and pancreatic substance, two grains. If the patients do not improve on this, sodium iodide, five grains, or syrup of ferric iodide, five m. three times daily, may be substituted. This must be kept up for a number of months, and the patient must return at stated intervals of from two to four weeks for observation. Some patients will take one form of iodine well, while others do better on a different medication. This can be determined only by observation and the prescription changed as needed.

GOITRES OF ADENOMA.

There were eight patients in this series. Four of these were recommended for admission and three went into the hospital. The usual adenectomy with partial thyroidectomy was performed in each case, leaving from one fifth to one quarter of thyroid substance *in situ*. These patients averaged 30.3 years of age, the eldest being forty-three, the youngest eighteen years old. All were females. The average duration of the disease was 5.5 years.

Thyroid adenomata are of two types: 1, fetal; 2, diffuse colloid. The former constitutes the greater number of cases. When arising from fetal adenoma, the growth is usually situated in one of the lateral lobes, but it may be in the isthmus of the gland. It gives an asymmetrical appearance, and on examination the consistency is found to be firmer than the surrounding substance of the gland. These patients first notice the swelling at about twenty-two to twenty-three years of age, and in the early years it does not give any discomfort. The patients usually seek medical aid for cosmetic reasons or because of pressure symptoms in the beginning of the disease.

Colloid adenoma gives a more diffuse enlargement of the thyroid gland. It is symmetrical and softer.

The treatment of adenomata in patients under thirty years of age without increased basal metabolism or local pressure symptoms should be continuous observation with determination of the metabolism readings every year. If for cosmetic purposes the patients demand removal before thirty years of age, the wish may be complied with. The thyroid gland is essential to the development of the body, however, and if possible should be left until after thirty years of age before performing a thyroidectomy.

*From the Goitre Clinic of Dr. Charles Gordon Heyd at the New York Post-Graduate Medical School and Hospital.

[1]Personal communication from Dr. Charles Gordon Heyd.

The cases advised for admission here were either for pressure symptoms or the patients were past thirty years of age and at an age when they began to show toxic symptoms. A high percentage of adenomata take on toxic changes between the ages of thirty-five and thirty-seven, and if an operation is performed before these changes have occurred it prevents permanent damage to the cardiovascular system, the liver and the nervous system. After operation, these cases should be treated with sodium iodide to avoid any iodide deficiency.

COLLOID GOITRE.

This group includes three cases. The average age was twenty-seven years, the oldest being thirty-five and the youngest nineteen years of age. Two cases were admitted to the hospital, one for diffuse enlargement in a woman thirty-five years of age, the other in a girl twenty years with pressure symptoms. Partial thyroidectomy was done on each of these cases.

Colloid goitre resembles somewhat an arrested stage of mild Graves's disease, but the exciting causes cease to operate after hyperplasia; the gland undergoes involution toward recovery. When involution is complete, the gland becomes a colloid goitre. This type of disease is met with in young women between the ages of eighteen and twenty-five. There is a symmetrical enlargement of the gland, of firm consistency, which may become enlarged at the menstrual period. It is usually seen in obese patients showing hypothyroidism. They occasionally give a picture somewhat similar to a beginning or mild Graves's disease, and have goitre, tremor, palpitation and nervousness but no exophthalmos. These cases are sometimes difficult to differentiate from the early stages of Graves's disease, and the basal metabolism is the only way of making the differentiation. In this condition the metabolism is usually minus or approximately normal.

The treatment is medical, and should consist of sodium iodide, five grains, or syrup of ferric iodide, five m. three times daily. The patients should be kept under close observation. They may be improved by this form of treatment if under twenty-five years of age, but if over twenty-five they will not improve. If there is a marked degree of enlargement, causing pressure symptoms, surgery should be advised. If the patient is over twenty-five years of age, and demands removal for cosmetic effects a partial thyroidectomy may be performed and the operation should be followed by some form of iodine treatment.

2.—GOITRES WITH INCREASED SECRETORY ACTIVITY.

Adenomata.—This series includes fourteen cases. The average age of the patients was thirty-five years, the oldest being forty-seven and the youngest nineteen years of age. All were females. The average duration of the disease was 5.7 years. Metabolism readings showed plus twenty-nine for the average; the lowest, plus nineteen, and the highest plus forty-nine. Partial thyroidectomy was performed on twelve of these cases. The other two did not enter the hospital after being so advised. The mortality was zero. These cases averaged eleven days in the hospital. Followup shows them free from symptoms at the present writing.

The clinical picture of this condition makes it easy to differentiate from Graves's disease. Usually there is a history of swelling in the neck for a number of years before consulting a doctor. The patients begin getting nervous from two to three years before seeking medical advice and come in complaining of palpitation and tremor.

The treatment of this condition is surgical as soon as diagnosed. After a number of years of continuous thyroid intoxication there is permanent damage to the circulatory system, the liver and the nervous system.

A recent report from the Mayo Clinic gives a mortality of .15 per cent. for 663 cases of simple adenomata following thyroidectomy; a mortality of 3.48 per cent. for adenomata with hyperthyroidism, in 201 cases; and a mortality of .96 per cent. in 523 cases of Graves's disease following partial thyroidectomy.

EXOPHTHALMIC GOITRE OR GRAVES'S DISEASE.

This series included ten cases, all of which were admitted for observation and operation. The average age of patients was thirty-two: the oldest being forty-six, the youngest twenty-one, with nine females and one male. The average duration of the disease was 1.6 years—the longest three years, the shortest one year. The metabolism averaged plus 45.5—highest, plus ninety, lowest, plus thirty. All these patients came to operation and the type of treatment varied with the metabolism findings. All were treated with either rest in bed or ligation before partial thyroidectomy was performed. Three cases, after rest in bed from seven to ten days, did not show signs of improvement, and they had bilateral ligation of the superior thyroids. One had thyroidectomy two months after ligation; one, one month after; and the third had a thyroidectomy after a two week interval before leaving the hospital. The remaining cases were treated by rest in bed, ice caps to heart and neck, luminal one grain every four hours, and forced fluids. These cases were considered safe surgical risks in view of the metabolism findings and the clinical pictures. The average period of rest in bed was 9.5 days—the longest fourteen days, the shortest seven days. The average stay in the hospital was 20.7 days—the longest thirty-two days, the shortest thirteen days. There was one death in this series.

CASE I.—Patient, M. Z., female, twenty-three years of age, had been nervous for two years. Operation for retroversion six months before entering hospital. She felt better for three months, then began going down hill very rapidly. Admitted to hospital on March 28, 1922. Metabolism reading, plus forty-five. On April 5, 1922, the metabolism was plus sixty; April 12th, plus forty, with patient much improved and the clinical picture favorable for operation. Thyroidectomy was performed, but the patient died of thyrotoxicosis thirty hours later. The pathological report was "Graves's disease, severe type."

CASE II.—Patient, S. S., twenty-nine years of age. On June 2, 1921, the metabolism reading was plus ninety; June 6th, plus seventy-four; June 16th, sixty-five, with clinical picture favorable for operation after eight days rest in bed. Bilateral resec-

tion was done, and the patient made an uneventful recovery, leaving the hospital twenty days after admission, with a metabolism of plus thirty.

These cases are cited to show that one may be misled by the metabolism readings if one fails to take the clinical picture and history into consideration. The history of Graves's disease is characteristic and it is usually one of the easiest forms of goitre to diagnose. The patients usually give a definite date to the onset of their trouble and attribute it to shock or some unpleasant experience. They present a picture of tremor, tachycardia, goitre and usually exophthalmos, with loss of weight. The treatment for the two forms of goitre is radically different, and the basal metabolism will easily differentiate Graves's disease from colloid goitre.

Graves's disease runs in cycles, with periods of remission in the severity of the toxicity. The first toxic crisis comes from nine to twelve months after the onset of the disease. The patients then have a period of improvement, and say they feel much better. This period of remission may last for from six months to a year, when there is a second toxic crisis, with increase in the severity of the toxicity, which lasts over varying lengths of time. Then there is a third crisis, and so on. If the patients do not die during these later stages, Nature tends to correct the hyperthyroidism by fibrous tissue replacement, and the patient becomes a chronic invalid from permanent damage to the cardiovascular system, the liver and the nervous system, with bizarre signs of hyperthyroidism.

In selecting the proper time to operate and the type of operation to be performed, it is important to understand these cycles of toxicity. A patient with a plus sixty metabolism who has passed through his crisis is a much better surgical risk than one with a plus forty metabolism and at the beginning of a crisis of the disease.

The treatment of this condition is surgical as soon as it is diagnosed, and the type of the operation depends on the clinical picture, the history, and the basal metabolism. The basal metabolism should be determined in all these cases when first seen, so as to have an index as to the severity of the toxicity with which one is dealing. A plus forty metabolism during the crisis gives a serious picture when the case does not respond with rest in bed and sedatives; and ligation of the superior thyroids should be performed and the thyroidectomy done at a later date. But if the patient is in such a toxic state that ligation is not deemed safe, she had better be carried over the crisis by absolute rest, sedatives and ice caps—and ligation of the superior thyroids done at a later period. The period of time which elapses between the ligation of the superior thyroids and the partial thyroidectomy will vary in the individual cases. Some cases may be operated upon within two weeks, while others will need two to three months' rest, but rarely longer. The maximum improvement is obtained at the end of ten to twelve weeks. The basal metabolism determinations will be the guide in this. If the metabolism is thirty to forty and declining, thyroidectomy is considered safe. Patients who have passed their crisis and have a metabolism of plus sixty or seventy, which drops rapidly with from seven to ten days' rest in bed to a plus forty or forty-five, are considered safe surgical risks for primary thyroidectomy, without preliminary ligation of the superior thyroids.

The use of the x ray and radium therapy and injections of boiling water into the thyroid gland have not given satisfactory results. Radium has been used since 1905 in the treatment of exophthalmic goitre, but the dose in this condition is still undetermined. X ray therapy has not as yet proved satisfactory. The dose has not been determined and it seems as if radium can be more easily regulated than the x ray. The one field in which they seem to be useful is in the treatment of hyperthyroidism of adolescent goitre in which there is a marked enlargement of the thymus gland. Injections of boiling water have proved painful and are not employed extensively because of this. It is a question as to whether there will be any permanent result from this treatment.

3.—GOITRES WITH DEGENERATION.

Malignancies.—This type of goitre is usually diagnosed without great difficulty, except in the early stages. The type of malignancy is the feature which holds our interest. This can be settled only by a biopsy. Crile states that ninety-five per cent. of malignancies of the thyroid are carcinoma; less than five per cent. sarcoma.

If there is a history of goitre for a number of years and it then takes on a rapid growth, with nodosities and infiltration, one is safe in assuming that it is carcinoma.

In this series we had two malignancies, but no biopsy was done on either. In one case the gastrointestinal x ray series revealed coincident involvement of the stomach. The patient did not return, and a followup disclosed the fact that this patient had died two months after coming to the clinic. The second case is under treatment at the present time, with x ray therapy. The patient has not cooperated and frequently fails to return for treatment until a followup letter is sent. In spite of this, he has gained ten pounds, the tumor has diminished by one third in size, and his general health has improved. He failed to have treatment for three months, and lost eight pounds in weight. At the present time he is again under treatment, one year following the onset of the trouble.

The average age of these patients was sixty-three years, the oldest being sixty-eight and the youngest fifty-eight years old—one female, one male. Metabolism readings were plus twenty, in the one case; in the other, the metabolism was not determined. The duration of the symptoms in the one case was fourteen years; in the other, one year.

Treatment.—These cases are usually far advanced when seen by the surgeon, and in a large percentage of them a thyroidectomy cannot be done. If the growth has not broken through the capsule, a complete thyroidectomy should be performed. In the inoperable cases, x ray or radium should be used. Such therapy should also be used postoperatively.

The mediastinum is often involved, and as x ray therapy has a deeper penetrative effect than radium it seems preferable to the latter in this condition.

CONCLUSIONS.

1. This series showed twenty-eight thyroidectomies, with one death, or a mortality of 3.5 per cent. A followup of this series of cases at the present

writing has failed to reveal any recurrence of toxic symptoms in those cases with thyrotoxicosis.

2. Adolescent goitre is a condition which should be treated medically unless there are pressure symptoms.

3. Colloid goitre should be treated medically with iodine if the patients are under twenty-five years of age. Past that age medical aid is of no value. Surgery may be employed for pressure symptoms or for cosmetic results.

4. Adenomata should be kept under observation until past thirty years of age, with yearly determinations of the basal metabolism, unless there are local pressure symptoms or hyperthyroidism. Past thirty years of age they are usually better treated by surgical measures.

5. Exophthalmic goitre or Graves's disease is a surgical condition and the type of treatment will vary with the metabolism determinations, the clinical picture, and the history.

Some Remarks on Hereditary Phenomena with Special Reference to Scrofula and Its Relationships to Endocrinology

By LEO HEINRICH WERDISHEIM, M.D.,
Graz, Steiermark, Germany.

In this article I desire to consider the transmission of diseases from parents to children, as well as the forms of disease which have arisen in the course of centuries. In the first place, my experiences at health resorts will serve as a basis for these observations, as in such places patients congregate who are afflicted with hereditary diseases.

In the health resort Gleichenberg, I observed disease pictures, which are typical of patients from the eastern countries (formerly Galicia), who are groups of people who have lived for centuries under the influence of miserable economic conditions. Their diseases affected chiefly the upper respiratory passages; chronic rhinitides with their sequelæ, such as polyposis of the nose; chronic bronchitides; pleuritides; diseases of the bronchial glands, and tuberculosis of the gastrointestinal tract, associated with tabes mesenterica in individual cases. The severest forms of tuberculosis occurred less frequently. Selection favored the restless migratory life of the worries and crowded conditions of living, which destroy health, had contributed to destroy the elements showing a weak vitality.

The various diseases mentioned above were inherited in the majority of cases, as the histories showed, from the grandparents and parents, and in many cases only a transient strengthening and restitution could be achieved, which is explainable by the acquired weakened constitution and the predisposition of the delicate mucous membranes of the upper air passages. Subsequent phenomena frequently attacked the other systems of organs. Inasmuch as tuberculosis is present mostly in the less accentuated grades, only because of the previously mentioned reasons, it has, in spite of the malnutrition of the majority of these Galicians, no longer been able to reach the more severe grades in general. The tenacity of organs inured to tuberculosis has offered resistance to the virus. The toxin has become anchored at the site of the absorption of the injurious substances, especially in the lymph nodes and underneath the skin, where it has become arrested and attached, to remain subsequently as a scrofulous structure. The scrofulous habitus persisted even in those patients who were in better conditions later. *In natura non est saltus* also applies here. A disease picture which required centuries for its development, cannot disappear so rapidly, but persists.

From this point of view the following forms of scrofula may be mentioned: external and internal, visible or manifest, and invisible. The following case serves as an illustration of the latter variety: A hereditarily scrofulous child, in spite of the most favorable conditions of life, becomes afflicted with a phlyctenular, that is, scrofulous conjunctivitis after several iodine baths, especially in damp weather.

Scrofula may also be classified as erethistic and torpid. The latter form occurs mostly in persistently undernourished individuals and the former occurs in persons in comfortable circumstances and displays a more latent character. With malnutrition the erethistic form of scrofula may change into the torpid form.

HEREDITARY NERVOUS DISEASES.

Before continuing the pathogensis of scrofula, the following observations on hereditary nervous affections showing a similar fate are worthy of mention. Groups of individuals living in seclusion, like the Galicians, and people living in Bosnia and a portion of the people living in the mountainous regions of Roumania, have, according to all appearances, repeatedly become infected with syphilis. Inasmuch as this disease runs an insidious and painless course in the first stage, it has been neglected frequently. The virus has persisted through centuries and became associated with typical degenerative forms, especially in the nervous system, such as tabes dorsalis, multiple sclerosis, spastic paralysis, Friedreich's disease, syringomyelia, and central asthmatic diseases.

On returning to the subject of scrofula, the fact must be emphasized that this, in association with the hereditary nervous diseases and particularly in their sequelæ, frequently depends upon a mixture of two stimulating substances and is the result of the influence of tuberculosis and of syphilis. The mixed product may be the result of the superinfection of tuberculosis upon a weakened luetic habitus. During the latter years of undernutrition, it was just among the descendants of the individuals with hereditary disease previously mentioned, namely, those afflicted with chronic respiratory and hereditary syphilis,

that a marked incidence of scrofulous individuals was noted, which expressed itself in stillbirths, premature births, retarded development of the bones and teeth, many forms of bone involvement, a deficient blood picture and deficient development of the brain and spinal cord with an impossibility of restitution. Two familial pictures may be mentioned as examples: 1. The grandmother showed scrofulous lymph nodes and a trigeminal neuralgia of the most severe form; the daughter and the grandchild was afflicted with a nervous urticaria. 2. The grandfather was afflicted with lupus of the pharyngeal mucosa, the son showed a tuberculous hemoptysis and the grandchildren were afflicted with scrofula and splenomegaly.

NATURE OF SCROFULA.

Further evidence that scrofula is a mixed form of tuberculosis and syphilis is furnished by the gummata of the Bosnians, which frequently resemble scrofula. As tuberculosis occurs very often in this weakened population, a mixture with the tuberculous virus is very likely. The more marked or weaker influence of one of these two factors is apparently decisive for the macroscopic appearance. These conclusions become demonstrative and clear when one sees the microscopic picture of these granulomatous structures. An absolutely uniform structure for gumma and scrofulous tumors is never demonstrable.

The purpose of this paper is not the differentiation between the more accurate pathological anatomy or the specific syphilitic associated symptoms. I need only to call attention to several forms of diseases, which may appear in scrofulous individuals and which lead to the conclusion that the tuberculous virus is also effective. Just as chronic osseous and articular phenomena must be thought of in iritis and conjunctivitis, just so must syphilis or a mixed form of tuberculosis and scrofula be thought of in certain gastrointestinal phenomena. The projection of secondary phenomena upon this theory alone is drawn insufficiently and too closely. All secondary symptoms, both of the nervous system and of the other groups of organs, must be tested repeatedly to determine whether and to what extent the Koch bacillus is an associated factor of disease, as wherever the organism is so seriously injured, as by the luetic toxin, this bacillus finds its most favorable medium.

HYGIENIC CONDITIONS.

What has been said of the Bosnians or Galicians in regard to the heredity of the scrofulous diseases, naturally applies also to all other populations, who live and suffer under similar unhygienic conditions. In some of these inbreeding has had a particularly injurious effect. The secondary symptoms of this mixed infection showed various manifestations according to the more or less favorable or unfavorable mode of life of these hereditarily infected elements. If, for example, we consider the gypsies, who are thus affected, we find that those who have settled down and entered upon a better mode of life, have shown less stigmata of hereditary involvement than their nomadic, unsettled fellows.

In regard to the fatality among isolated individuals, this occurs most readily in those in whom the endocrine organs are diseased. From this point on the hereditary affection seems to be attended by its most serious and worst sequelæ; namely, these organs stand guard over the metabolism of the human body; they act as regulators and hold out the longest.

PRELIMINARY TRTEATMENT.

Inasmuch as the symptomatology of the disease is still in its infancy, the therapeutic test must be instituted as soon as possible; no time is to be lost in treatment, if the organism is to be restored and supported. The preliminary stage of the treatment in the vast majority of scrofulous individuals, that is, mostly in tuberculous, luetic, run down individuals, especially when the disease is hereditary, must lie in organotherapeutic treatment. Inasmuch as the individual immunosecretory organs down to the most minute changes are not demonstrable at the time, but nevertheless their associated action is definite, the multiglandular preparations must be used. After this preliminary treatment, the combined salvarsan tuberculin treatment, particularly iodine (Mirion) tuberculin treatment is to be preferred.

I would particularly emphasize the fact that the ontogenetic relationship between the degenerative nervous diseases and the luetic scrofulous diseases is also influenced by combined tuberculin treatment. Consequently, in the luetic degenerative forms of tabes an admixture upon a weakened base, which will influence the tuberculosis, must be used. The therapeutic effect, to a certain extent, proves the ontogenetic relationship of these disease groups and both of these groups are concomitant.

THERAPY.

These diseases are favorably influenced by iodine therapy and iodine preparations, either in the form of iodine baths, sea water containing iodine, or iodine drinking waters in the form of mineral waters, iodized cod liver oil, or other iodine preparations. In regard to the food of patients, who are afflicted with such diseases, it might be said that a diet containing an abundance of vitamines is to be recommended for the rest of their lives, including fresh meat, fresh fruits, lemons and oranges; sterile fluids, as, for example, grape juice, have a good effect. All of those foods which are rich in vitamines also favor the remineralization of the organism and with it also the endocrine organs.

In the interest of a healthy and strong posterity, namely, from a eugenic viewpoint, all individuals afflicted by a hereditary taint, with multiple swellings of the lymph nodes, be they luetic, tuberculous, or scrofulous, should be eliminated from posterity. If a general lymphadenitis is present (special attention being given to the palpation of the cubital lymph nodes) then the entire organism and with it the motor of all life—the endocrine organic system—is diseased. If, in this stage of hereditary diseases, reliance is placed upon the Wassermann reaction, then latent diseases, which often lie dormant for one to two generations, will again flare up in the third and fourth generations. The preparatory preliminary treatment with multiglandular preparations, the most important constitutents of which are the synthetic indifferent combinations of iodine, must not be delayed. It may be assumed that organotherapy will have its greatest successes in the field of hereditary diseases.

The Anxiety State and Endocrine Disturbance

By ERNEST SNOWDEN, M.B.,
London.

It is inevitable that an investigator in examining any subject should approach it along the path with which he is most familiar, and one of the dangers against which medical practitioners have to guard themselves in this present day of specialization in medicine is that of seeing a patient from one point of view only.

It is essential that every specialist who hears the symptoms and observes the signs in any patient should interpret them from his own point of view, but endocrinology appears to be in danger of becoming too isolated, a phase through which all specializations in medicine have passed, and it is important for the healthy development of the subject that it should retain a width of outlook within the limits of its sphere, in order that it may be successfully linked up with all that is best in medicine. More especially must any separation of this science from the science of psychology be guarded against.

The two subjects appear to be so closely linked together that it is probably just as unwise for an endocrinologist to attempt to treat his patient without a knowledge of psychology, as it undoubtedly is for a psychologist to attempt to treat psychological disease without studying endocrinology.

Many of the cases which are sent to the psychologist for treatment and which appear at first sight to be essentially psychological in character, require some treatment to assist the glands of internal secretions in their efforts to restore function and balance in the organism, but this treatment alone would fail if psychological means were not employed at the same time. In many of these cases it is a question of interest to decide from what point the disturbance starts, and, speaking as a psychologist, I should say that in the greatest number it is a psychological disturbance which originates the illness. It is true that in greater or less degree, in every case of anxiety neurosis and of socalled psychasthenia, as well as most of the psychoses, the patients suffer from disturbances of the endocrines.

The conversion hysterias which form perhaps half of all the cases requiring psychological treatment do not seem to be affected so profoundly, because they go through the changes belonging to the emotions that they feel without any permanent disturbance remaining, owing to the fact that their emotions are readily shown and that between the demonstrations of their illness, the mind is not disturbed. It is only where there is control or repression of the actions to which the emotional reaction in the mind gives rise, that serious or permanent disturbance of the endocrine balance occurs. Perhaps it would be wise to exclude from this generalization the type of case in which the emotional reaction is readily shown by the patient, but where the same emotional disturbance occurs repeatedly, as for example, in the man who went through intense fear during the war, which he was quite unable to hide, but who was compelled to return again and again to the trenches and go through the experience afresh. Even in such a case it seems likely that it was the anticipation of the terror which caused the endocrine disturbance rather than the actual emotional state itself.

To return to the statement that those individuals in whom emotion is readily shown do not suffer from permanent disturbance of their endocrine balance, possibly the best evidence in proof of this can be obtained by the use of the socalled psychogalvanometric reaction. Briefly stated, this means that if you pass a constant electrical current through the human body, the resistance of the body to the current is lowered during emotion, and as this phenomenon seems to be a part of the changes in the body resulting from emotional states, it can be taken as a measure of the degree to which all the other emotional changes occur. By using this reaction it will be found that mankind may be divided into two classes: The emotional and the controlled.

In the type of patient who readily shows emotion and in conversion hysteria, little or no change in the resistance to the current is observed, but in the controlled types, especially in those cases in which emotion is not recognized by the individual himself, there is a profound change in the resistance to the current during emotion, and, therefore, in all probability in all those parts of the body which react to the stimulus causing the emotion.

Thus what may be called direct or straightforward disturbances of the endocrines occur commonly in the anxiety state. The psychasthenic falls into the same category as the case of the soldier mentioned above, for it must be recognized that the psychasthenic would run away from his fear if he could, and is only restrained from doing so by the knowledge that if he did he would carry his fear with him.

In the anxiety state the presence of the emotional factor is only half recognized by the sufferer. He makes every effort to control the emotional disturbance, and in consequence becomes slowly poisoned, until clinically, the picture of the anxiety neurosis is established.

It is easy to bring forward further evidence to support the truth of what has just been stated. The emotional states were intended by Nature to serve a definite purpose and the addition to the circulating fluids of secretions from the glands of internal secretion was intended by Nature to assist in the activities that the emotions engendered.

It was intended further, in the primitive state, that the actions corresponding to these emotions should be carried out immediately and to their fullest extent, and where this occurs the whole cycle of changes is complete, the circulating substances which are intended to enable the body to live at its highest level are used up and when the activity is over the body returns to its normal state without any damage having occurred.

It is to the control of these emotions, or perhaps more correctly, to the control of the activities which should naturally follow these emotions, that serious disturbance of the endocrine balance is due.

From this point of view the most important emotions are three in number: 1. The emotion of fear belonging to the instinct of selfpreservation. 2. The emotion of sex belonging to the instinct of reproduction. 3. The emotion of anger belonging to the instinct of protection.

By this last, I mean the instinct given to us in order that we may protect our own property, whether that property is a stone axe, a hunting ground, a mate or an ideal. Nature intended that each of these emotions should be associated with violent physical activity: Fear with running away; sex with running or with a physical contest; anger, with violent physical conflict.

Grief is simply anger which has been foiled in its object and grievance, which is one of the most damaging emotional states from this point of view, an anger directed against a community or against a society or against a body of people, an anger which cannot be satisfied because it cannot result in direct physical action against any one individual.

Anxiety may be looked upon as a chronic form of fear; fear which is low in intensity but which is constantly present.

The fact that the emotion which is denied its physical outlet results in profound physical and mental disturbance is well illustrated in the case of two schoolboys who have had a violent quarrel. If they are permitted to fight it out they can shake hands and are good friends afterwards, but if this is prevented, friendship between them is impossible. We say that there is "bad blood between them," and this appears to be a true statement of the fact, their blood being charged with substances, poured into the circulation by Nature for the definite purpose of physical activity, which have not been utilized for that purpose.

We instinctively feel the need for violent activity whenever these emotions are aroused and in the better controlled classes of society, if the husband and wife quarrel, the wife usually gives way to tears, thereby using up her endocrines in an emotional outburst, while the husband kicks the dog down the front steps and goes for a five mile walk.

To sum up this part of the subject, we can say that when one of the primitive emotions of fear, sex or anger is aroused in the human mind, the person either reacts quite simply to the emotions and carries out the action it involves, in which case the reaction is complete, the internal secretions circulating in the blood stream are used up, the body returns to a satisfactory relaxation and the mind to complete placidity; or, where these emotions are controlled and the actions prevented from being carried out, damage to the organism results from the fact that oxidation and elimination of the circulating secretions is a slow and troublesome process.

It is fortunate that our social code permits the expression of grief and anger so that we are able to express anger more or less directly, and, without much divergence of the original idea, we can use this path for the expression of fear and sex as well. More especially is this possible because the physical reactions belonging to these three emotions are so closely allied to one another that they are readily confused by the individual, and the action path of anger can thus be utilized by all three.

To consider now more particularly the anxiety states. When repression occurs the approach of some emotional memory or some emotional wish to consciousness is prevented, but the stimulus which causes their approach to consciousness also arouses the physical change which belongs to them, and because this physical change occurs at the most primitive level of the nervous system, its appearance in the body cannot be checked.

In anxiety states these physical reactions of emotion are never followed by the complementary activity. They are observed by the patient to be the signs of some physical disease which belief, in its turn, engenders fear or anxiety and sets up a vicious circle of greater or less intensity in which anxiety and physical change alternate.

It is when such a circle has been in action for some time that some one gland, or set of glands, becomes raised to a higher level of activity than is normal, and it is then that the disease is recognized clinically as a disease of the internal secretions.

ANXIETY AND TOXEMIA.

It is now necessary to consider the part played by the emotional states in the production of endocrine unbalance when this is due to the absorption of toxins, and to do this it will be necessary to consider the physical changes produced by emotion in a little more detail.

The physical changes occurring in all three of these emotions are so much alike that fear can be taken as an example. If the factors which go to make up this bodily reaction are analyzed, we will be able to discover how each one is likely to affect the organism. To do this let us go back to the primitive reaction of fear, and see what occurs in the body. It is the intention of Nature that the animal shall run fast and far, and it is to that end that the whole activity is directed.

The presence of danger stimulates the lowest levels of the nervous system. There is an outpouring of secretions from the suprarenal glands, and in consequence from most of the other glands of internal secretion. The heart is stimulated to more rapid and stronger action in order that the skeletal muscles may be supplied with food, so that they may be swept clean, and their activity prolonged. Breathing becomes hurried, so that the need for the greater exchange of oxygen and carbon dioxide in the lungs may be met. There will be dilatation of the peripheral bloodvessels which causes flushing, and sweating will occur in order that the blood may be cooled.

These are the signs which, as we observed above, are recognized by the uninstructed patient as the signs of some physical disease, but there is a further series of phenomena of which the patient is for the most part ignorant, but which makes it possible for this other form of disturbance of the internal secretion balance to occur. The digestive functions are held in abeyance; the muscle walls of the intestines relax, except in the case of the intestinal sphincters, which show tonic contraction; the total effect of which is to produce intestinal stasis.

The intestinal stasis causes the contents of the gut to collect at certain well defined points; these are noticeably the stomach, the lower end of the ileum, the cecum, the transverse colon and the sigmoid

flexure. These contents are only partly digested because of the emotional inhibition of the digestive functions, and they give rise to a toxemia because of the absorption of the products of their incomplete chemical treatment.

Bacteria from the mouth or from the ingested food are readily able to pass the barrier of the stomach in which the lowered digestive functions are not able to destroy them, and the bacterial content of the gut is thereby increased. Furthermore, at the points in the intestine where stasis is most observable the bacteria have greater opportunity for activity, and the slow movement of the intestinal contents assists the absorption of the toxin which they produce. The weight of the overfilled intestine pulling upon the attachments at these points causes enteroptosis, and a chronic form of stasis. As a result of this the excretory organs are overloaded and the thyroid and suprarenal glands in their efforts to take part in this excretion become first of all enlarged and active and later on are found to be enlarged and exhausted.

Thus the anxiety state is able to take a large share in the setting up of conditions in which toxemia with all its effects on the glands of internal secretion is produced.

To take the thyroid, which is the most observable gland in the hierarchy, and observe the changes in it, we find that the hyperthyroidism and the subsequent hypothyroidism which result are not readily distinguishable in the two cases where they arise from 1, an anxiety state, in which bacterial toxemia is not a particularly strong feature, or 2, from bacterial toxemia, in which the anxiety state is not noticeably established.

Finally, it will be recognized that before this cycle can be begun some lowering of the general condition of the organism must have occurred, and in taking the history of such cases, if they are approached with a psychological point of view well in mind, it will be found that some change has occurred in the circumstances of the patient which might be expected to set up an anxiety state, and that it is usually from such a beginning that the condition takes its origin.

When the cause which has originated this anxiety state has already been removed, then the condition can be successfully treated by the bacteriologist and endocrinologist, but unless this fact can be definitely established, any attempt to treat such cases without the aid of psychotherapeutic measures will too frequently end in disappointment.

Asthenocoria*

A New Sign of Suprarenal Insufficiency with a Few Considerations on Endocrine Therapy

By CARLOS F. ARROYO, M.D.,
Tampa, Fla.

Not all physicians admit the existence of a state of hypoadrenia and on account of this fact I would like to explain what I understand under that denomination. Our conception of this condition only goes back to 1855, when Addison described the disease that later on received its name. This was considered the only form of adrenal insufficiency until Dieulafoy and his pupil, Bressy, observed some cases presenting the characteristic signs of Addison's disease without pigmentation. These cases they called abortive forms of Addison's disease.

Sergent and Bernard, following the investigations of Brown-Séquard continued by Abelous and Langlois, showed that the disease described as Addison's, was in reality a complex syndrome in which two types of symptoms could be made out; those resulting from an adrenal insufficiency (among which asthenia and circulatory disturbances) and symptoms resulting from an irritation of the sympathicosuprarenal nervous system, among which pigmentation was the most characteristic.

They described adrenal insufficiency as: the expression of the decrease or the supression of adrenal functions and separated it from the syndrome of Addison, characterized by pigmentation. They considered the bronzed disease, described by Addison, as an association of the syndrome of adrenal insufficiency with that of a sympathetic affection. This conception to my mind, is erroneous, as the relation between the suprarenals and the sympathetic nervous system is so intimate that there cannot be an adrenal insufficiency without the sympathetic being affected.

Later on, especially since the war, many authors have described several syndromes of hypoadrenia. So Eppinger and Hess, of Vienna, Sajous, of Philadelphia, Professor Josue, of Paris, who has described an asystolia of adrenal origin, occurring in cases of certain cardiopathies in soldiers, the socalled hypoadrenal types of Satre, the Italian authors, Frugoni and Gardeghi, who have connected a state of hypoadrenia with typhoid fever and Da Fonseca, of Brazil, and Ricoldoni, of Uruguay, who described an influenzal adrenal insufficiency. Other authors, Sergent, Hutinel, Ribadeau-Dumas, and others, have found a condition of hypoadrenia accompanying almost every infectious disease. This is not surprising, as the adrenals play such an important part in our means of defense that Cannon has considered their hormone an emergency hormone.

The cases of hypoadrenia studied by me are those presenting a well defined syndrome of suprarenal insufficiency with progressive asthenia, rough breathing at both apices (the socalled pretuberculous cases), arterial hypotension, digestive disturbances, low temperature, weak heart sounds and the syndrome so well named, hyposphyxia, by the late Professor Alfred Martinet. Sergent's adrenal white line and pigmentation were not found very often but Pende's sign (goose flesh, after rubbing the skin) and dermographism were present in most cases. In all of them I observed a sign that I want to report

*Read before the Hillsboro Medical Society.

here and that so far as I could ascertain, nobody else has described. I offer it to you for consideration and further confirmation. When exploring the pupillary reflex I found that the iris of these cases, although reacting readily to light, the contraction was flabby, lazy, in a word asthenic. By making the patient look at the light we see that immediately after the initial miosis the pupil starts to dilate slowly as if it doesn't want to, seems to try to contract again, but dilatation gains the upper hand and after a fight between miosis and mydriasis lasting for about forty seconds, the pupil remains dilated in spite of the persistence of the exciting agent. This sign is constant and present in all cases of hypoadrenia and in all its clinical forms. In the normal individual it does not appear as I have investigated. All patients presenting this sign that I would like to call asthenocoria, have been benefited by suprarenal medication.

A few clinical histories will present the matter more clearly.

Case I.—Miss M. B., fifteen years old; menstruation started at twelve, regular until five months ago when it disappeared. She was referred to me by Dr. Andrews, and I examined her thoroughly. The family history and personal history were negative. The present illness started five months ago when she lost her ambition and appetite, menstruation stopped, and she felt a sensation of fullness after meals. At the start pregnancy was suspected. The skin of the patient was somewhat darker than the average Latin, but she was a brunette and no further attention was paid to this fact. The chest examination disclosed rough breathing in both apices. The nails and lips were slightly cyanosed (Martinet's hyposphyxia). The heart beat slowly, no murmurs. The hands were cold and dry. Sergent's white line could not be detected in spite of the dark skin. Pende's sign was present; when examining her pupil asthenocoria was found. A diagnosis of hypoadrenia was made. Adrenalin was prescribed, ten drops three times a day, and fifteen days later the patient was seen; she didn't feel better. I prescribed total adrenal gland, desiccated, thirty centigrams three times a day. The patient came back after a month and said she felt much better. She liked to go to school and to work at home, and she had developed an enormous appetite. She had gained six pounds. Menstruation was still lacking. She was told to continue the treatment, and I saw her two weeks later and the improvement continued. She had gained altogether thirteen pounds, and her appetite was ravenous. Asthenocoria had disappeared, the pupillary reflex was normal, menstruation still lacking. I combined the adrenal extract with ovarian extract, ten centigrams three times a day. I saw the patient a few days ago, and the improvement had continued; menstruation had returned, although it was scanty.

Case II.—Mr. J. D., eighteen years old, came to me as a suspicious case of tuberculosis. I found a tall, thin young man, dark skin, presenting rough breathing on both apices and a few fine moist râles scattered over the right upper quadrant, slight impairment all over right chest. Felt constantly tired, had no ambition to work and among other signs of hypoadrenia, I found Sergent's white line, Martinet's hyposphyxia and asthenocoria. The temperature was subnormal (35.4° C.), pulse rapid (100), blood pressure, systolic, 105, and diastolic, 70. The sputum was sent to the laboratory for examination and it comes back negative; but as the findings on the lungs were suggestive of tuberculosis, I recommended rest, fresh air, a rich diet, and prescribed total adrenal extract, thirty centigrams three times a day. A month later I saw the patient again and I found that the lung findings were characteristic of tuberculous involvement of the right upper lobe. He now showed a temperature of 37.5° C. in the afternoon, his appetite had improved in spite of all this, and he had gained one and a half pounds. The pupillary condition had changed from asthenocoria to anisocoria, the pupil remained relaxed in the right eye while the left pupil contracted normally. The sputum was again sent to the laboratory, and reported positive for tubercle bacilli. I think that this was a case of tuberculosis from the start, but his lack of defense was such, that he was unable to react actively to the toxins. Only when his adrenal function was reestablished was he able to respond with a slight glimmer of energy to the attack of the infective agent. The patient was put to rest in bed and adrenal treatment continued. He is still improving although the fever persists.

The two foregoing histories are typical of the kind of cases studied by me under the general heading of hypoadrenia and, therefore, I shall not tell the same history again. However, I recall the case of a woman who gave a history of hypoadrenia with menstruation and without asthenocoria. She was placed on adrenal extract and grew worse. In view of this fact I changed the treatment to ovarian extract combined with foreign protein therapy. The woman improved in so far as to be able to take up her work again. This case is interesting because it is the only one of my series in which the patient was not a Latin, although her hair was black and her skin dark: she was a Slav.

I have no theory to offer as to the mechanism of asthenocoria. I don't know whether the relaxation of the pupil is provoked by stimulation of the sympathetic or by muscular fatigue as a result of a decreased adrenalin supply. While discussing this paper with Dr. Taylor, he told me he had observed a similar pupillary reaction in cases of high blood pressure. Shortly after this discussion, I had occasion to study the behavior of the pupil in such a case of high blood pressure and I found that although there is in such cases also a fight between miosis and mydriasis, miosis remains victor. All my patients had a low blood pressure.

The treatment of hypoadrenia should tend, first, to remove the cause of the condition if possible, and to be completed by the use of suprarenal powder of the total desiccated gland. Generally speaking, when administering organotherapy the entire organ should be used. An aqueous extract of the active principle, although producing wonderful physiological results in a given direction, is incapable of substituting the action of the whole gland.

There may be other active principles besides the one we know. The objection that by giving the gland by mouth, the hormones may be destroyed, cannot be admitted because being of the nature of

enzymes or ferments, they are absorbed and eliminated without change after the catalytic action has been exerted. This catalytic action may be multiform, either by stimulating the sympathetic nervous system alone, the secretory activities of the specific gland, the cellular activity of said gland or all of these functions together. We must remember that the endocrines are closely related, especially the suprarenals, to the sympathetic nervous system and that their function very likely is not merely limited to the secretion of a given substance, but on the contrary, they are capable of producing nervous impulses regulating the different functions of the body. These impulses cannot be produced by the socalled active principle alone but only by the glandular cell as a physiological complex with all its biochemical, physical, and even mechanical and morphological constituents.

Gonads of Women From an Endocrine Viewpoint

By JANE NORTH BALDWIN, M.D.,
New York.

There is a very close parallel between the gonads of the two sexes both as to their origin and to their function. Each has its external secretion and, as Brown-Séquad has so very ably proved, each has its internal secretion as well. His experiment upon himself has been duplicated by various methods, Steinachs and others, but the anatomical difference makes the demonstration of internal secretion of the ovary more difficult.

Embryologically both the ovary and testes develop from the Wolffian ridge. The biochemistry of the internal secretion has not yet been completely worked out, nor has the active principle been found as has the adrenalin content of the suprarenal glands, the pituitrin of the pituitary, the thyroxin of the thyroid or the more recent discovery of the insulin of the pancrease; this, however, can only be a question of time. We now have the lutein of the lutein cells of the corpus luteum and its power has been more markedly proved by veterinarians than by the medical profession. As we study the formation of the corpus luteum we find it develops in the graafian follicle after the escape of the ovum and consists of large epithelial cells filled with fat pigments and cytoplasmic elements. We all know its life cycle and it has been found that the persistence of corpus luteum of pregnancy causes sterility in cows and upon its removal fertility returns.

Marshall and Jolly assert that the injection of corpus luteum in castrated females causes congestion of the genitalia resembling the phenomenon of rut. In our own therapeutics, we certainly use it most successfully in the physiological change at the menopause as well as in the nausea of pregnancy and other conditions. The interstitial cells of the ovary corresponding to those of the testes are believed to develop from false yellow bodies, that is, from the atresic follicles from which the ovule has not been liberated but absorbed and changed into strands of cells granular in nature, having lipoid content. By others they are supposed to be modified connective tissue cells. Most histologists now believe the interstitial cells of the ovary produce lipoidal secretion in common with those of the testes and the suprarenal gland. The therapeutic power of the whole gland of the ovary or that of the ovarian residue or that of the corpus luteum alone is greatly disputed and each has its strong advocates as well as those who consider there is no value at all in any of it. Novac says, "The difference between the remarkable testimonial of the patent medicine and many socalled clinical reports, is that in one instance the gullibility of the laity is displayed and in the other the credulity of the equally human medical profession." When he cites the following conditions for which ovarian extracts have been given we do feel we are standing on uncertain territory. Amenorrhea, functional bleeding, dysmenorrhea, infantilism of the generative organs, vasomotor and nervous disturbance of the menopause, sterility, vomiting of pregnancy, pruritis vulvæ, deficient mammary secretion, epilepsy, Graves's disease, but we must have some really scientific data from which to work and light is certainly coming from both laboratory and clinic.

As with the other incretions of ductless glands and those which have excretions as well, the gonads may have hypersecretion or hyposecretion or at times one and then the other dysfunction with characteristic symptoms accompanying and the hypersecretion or hyposecretion may be from a cause primary in the gland itself or secondary from the influence of other glands, giving us the multiglandular syndromes (Timme). The gonads of either sex seem to have little influence on the individual either physical or psychical until the advent of puberty, at which time the secondary sex characteristics develop.

However, the removal of the gonads in the male before puberty produces characteristic eunuchs of either the tall, thin type or more frequently the heavy, fat type. Castration before puberty in the female is so uncommon, if at all, that we have little scientific data. Roberts reports a sect in India, which castrated little girls who grew into tall, thin, masculine types of women with no breast development or secondary sex characters. However, there has been much work done experimentally upon animals and we know that we get disproportionately long extremities, retardation of epiphyseal closure and other conditions. Removing ovaries in birds causes appearance of male plumage. The agenitalism produced by castration after puberty gives us the symptoms of artificial menopause, the change of voice being marked, also hirsutism and obesity. The agenitalism due to congenital absence of ovaries is greatly

questioned and Olshausen believes that a rudimentary uterus or vagina can be found. Sunquists reports the case of a woman thirty-four years old, who was 183.6 cm. tall; upper length 118 cm.; never menstruated, no inclination for men, small mammæ, small nipples, small genitalia with hypertrophied clitoris, no introitus vagina or hymen. Neurath reports the case of an eleven year old girl with eunuchoid obesity, fat deposits on lower abdomen, buttocks, mons and thighs, with deep furrows about the mons.

I have had a case in a girl of twenty who was slightly above medium height, with fine features and skin, slender boyish figure, scarcity of hair over body which was of female type, and no introitus vaginæ, of course no menses and no generative organs palpable or any mass over the suprarenals. I regret having been unable to follow up the case with x ray and laboratory findings, but the patient was very sensitive and had no sympathy with any scientific interest.

In hermaphrodism and pseudohermaphrodism we may have, 1, ovary on one side and testicle on other; 2, ovary and testicle on one side, either, both or neither on the other; 3, ovary and testicle on both sides.

The advent of puberty differs in different climates, in this climate averaging about the age of thirteen. We have not space to describe the cycle in detail, anestrum, proestrum, astrum, etc.; but we do know that grossly the uterus about doubles in size within a few months, that secondary characters appear, that the psyche of the person changes and that other glands enlarge, particularly the breasts and the thyroid. The thymus is believed to atrophy at this time. We may have general symptoms of chlorosis and occasionally marked psychical disturbances.

Conversely we have the other extreme of sexual life, the menopause, at which time the gonads normally atrophy producing the well known physical and psychical changes. It is here that the hormone of the ovary is of inestimable value, corpus luteum five grams three times a day or lutein one ampoule every second or third day, ovarian residue five grains three times a day.

The functional uterine bleeding at menopause can be well controlled with pituitary extract one grain three times a day whole gland or one quarter grain three times a day of anterior lobe, of course eliminating first any possibility of organic trouble or malignancy.

Geist believes that this bleeding is due to absence of corpus luteum. Schroeder also reports some cases in which corpus luteum was absent. The interrelation of the glands of internal secretion is also shown with the functional bleeding at puberty in which the use of thyroid extract is sometimes valuable. I recall a case I had several years ago in a girl of eighteen who had continual uterine bleeding. All kinds of internal treatment was tried with rest, ice bags and douches, and finally dilatation and curettage. Relief was only temporary and to my amazement she returned to me after another similar operation, only this time one ovary had been removed and she was told that if no relief was obtained a hysterectomy should be performed. There was no relief, but instead of a hysterectomy we gave her two and a half grains of thyroid extract daily, which controlled her perfectly. She is now married, has two fine children, but is obliged to continue her thyroid feeding.

Besides the physiological amenorrheas we have the amenorrheas due to: 1, general disease, chlorosis, tuberculosis and others; 2, acute fevers; 3, infections, gonorrhea, sepsis; 4, hemorrhage, into the ovary; 5, climacteric changes; 6, psychical influences, shock, mental diseases, and 7, dysfunction of the ductless glands, the hypothyroids producing ovarian hypofunction, the hypopituitary as seen in Fröhlich's syndrome, pituitary type of hands, distribution of fat between waist and upper part of thigh, etc., and no menses, and hypoplasia of the adrenal cortex producing amenorrhea.

Dysmenorrhea is another gonadal symptom in young women, married or single, which may be due to a neurotic factor or mechanical cervical obstruction, or uterine hypoplasia of pituitary influence, which should be treated with pituitary extract.

Primary menorrhagia and metrorrhagia is probably due to ovarian hypersecretion, therefore pituitary and thyroid extracts should be given. In primary ovarian hypersecretion we have precocious puberty that is advent of menstruation and secondary sex characteristics before the age of nine and usually a subnormal mentality. Brohl found a cystic ovary in the case of a seven year old girl who returned to normal after its removal. Pubertas precox is more often seen, however, in connection with tumors of the pineal gland or the suprarenals, teratomata or hydronephromata. Neuman reports twenty-two cases, Horrax reports a case in enlargement of the sella.

Von Haller has reported the case of a girl who menstruated at two, became pregnant at eight, and lived to be seventy-five, and Beekman, the case of a girl six and a half, with the bodily development of eleven; x ray showed enlarged sella. With these tumors we also see virilescence, precocious bodily and mental development, with hair on mons, face and axilla, but no menses or sexual maturity.

In women status thymicolymphaticus is demonstrated by peculiar character of skin of the body, slender thorax and extremities, scantiness of hair in the axilla on pubes and genitalia with hypoplasia of the genitalia.

The effect of the gonads *per se* on gigantism or infantilism is much questioned. Their destruction in preadolescence would cause hypertrophy of the hypophysis which in turn would affect growth, therefore their action would seem an indirect one. Much experimentation has been done on both the mammary glands and with the placenta in an endeavor to prove they possess a real incretion. That there is a direct relationship between uterus, ovary and mammary gland cannot be doubted, as witnessed at puberty in enlargement of the breasts, in their congestion at time of the menses, in their functioning during lactation and their atrophy after menopause. Removal of the ovary is followed by atrophy of the mammæ. Ovarian transplantation has been followed by enlargements and secretion of milk. Mechanical or electrical stimulation of the breasts produces uterine congestion and contractions.

Reports of placenta experiments are also conflicting, but Hammet believes it has an incretion which

causes uterine hyperplasia and that the rate of growth in breast fed infants is enhanced by feeding the mother desiccated placenta.

The field of endocrinology from a scientific viewpoint is a relatively new one, across which we should walk most carefully and not gallop on the back of empiricism and exaggerated claims. However, if we dig deep into laboratory and clinical findings there is great promise of unearthing much of genuine value.

NEUROLOGICAL INSTITUTE.

Rôle of the Endocrines in the Growth and Nutrition of Children

By HYMAN GOLDSTEIN, M.D.,
New York,
Assistant Physician, Children's Clinic, Lenox Hill Hospital, O. P. D.; Visiting Pediatrist, Day Nursery Daughters of Israel; Chief Visiting Physician, Home, Sons and Daughters of Israel.

Until quite recently little was known about the complex processes involved in cellular nutrition and growth of children. The ductless gland secretions play a great rôle in preparing the tissue cells to utilize the food elements.

Malnutrition in childhood is more than a question of insufficient food or deficient vitamines. We find it in a great proportion of the well fed or well to do, as well as among the poor, and it is not rare to find an excellent state of nutrition where the food supply is scanty. The malnutrition which is severe enough to be reckoned as a factor in faulty development is usually the result of a hypoplasia or endocrine insufficiency. The vitamines, so vital for the sustenance of life, known as the fat soluble A, and water soluble B and C, and even vitamines D and E recently described, are present in most foods, particularly animal fats, milk, fresh green vegetables, polishings of rice, maize, tomato, potato, yeast, orange, lime, and lemon juice. These vitamines are essentially stimulants and restoratives to the production of hormones and metabolic processes. There is close connection between the function of these and the ductless glands, a fact demonstrated experimentally by McCarrison, Funk, Emmet and Allen. It seems that the hormones prepare the tissues, giving them receptive power to receive and properly utilize the vitamines. It is paramount, for the best interests of the patient, that the physician, as well as the consultant, should be able to detect the early changes of the ductless gland disturbances that give rise to the various nutritional disturbances so common during infancy and childhood, so that remedial aid can be effective. Among these disorders are marasmus, rickets, acidosis, and diabetes, hypoadrenalism and hyperadrenalism, hypothyroidism, and hyperthyroidism, lymphatism and dyspituitarism; hemopoietic and pluriglandular disturbances.

Cases of marasmus at autopsy frequently showed an abnormally small thymus. We all know how these cases resist all forms of treatment. In many of my cases small doses of thyroid with thymus or lymphatic gland substance gave excellent results.

As to rickets, Harrower describes it well, stating: "It is a nutritional disorder of children, a form of starvation, hence before it can be treated effectively we must know what factors are prominent in the production of the disturbed metabolism and what elements can be given acceptably to replace those that are deficient." From an experimental viewpoint, rickets is now understood to be a result of endocrine disorder. It is definitely known that the ductless glands influence the metabolism of mineral salts in the body. There is no doubt about the important rôle calcium salt metabolism, and the ductless glands that govern this, play in the human economy. Howland and Kramer found in the serum of young children a low content of inorganic phosphorus in cases of rickets. When treating rachitic children we must aim at the calcium metabolic disturbance and improve the lymphatic circulation. Thyroid extract gave excellent results in many of my cases and in obstinate ones a pluriglandular formula, containing extracts of thyroid, parathyroid and lymphatic gland substance, helped. In the interim glycerophosphates of lime and soda or compound syrup of hypophosphites may be given.

In the hypoadrenal type of malnutrition the children are pale, emaciated, are easily tired, asthenic, chilly, and show a low blood pressure, capricious appetite, cold extremities, sluggish mentality, often associated with nephritis, because of the accumulated waste products. These patients are helped with thyroid and suprarenal extracts, good food, enforced rest and care of the emunctories. The opposite type or the hyperadrenal child, is tall, dark, thin, active and delicate, with long silky hair. These children often complain of indigestion and anemia. In these cases pancreas substance in large doses is effective.

The lymphatic type of malnutrition includes cases in which the liver, spleen and lymphatic glands are definitely involved. These children appear to be undernourished and phlegmatic. They breathe like asthmatics and are subject to various blood and lymphatic dyscrasias. The lymphatic glands, including tonsils and adenoids, may be enlarged. They are predisposed to tetany and convulsions. The asthenic type improves upon the combination of Leydig cell extract, lymphatic gland and thymus. In the general treatment of these cases organotherapy must be directed at the most obvious phases of the symptomatology to correct the disturbance.

Thyroid insufficiency produces the lazy, obese and constipated type of children. They are easily fatigued, have poor appetites, are sluggish mentally, often complain of arthritic and muscular pains, with frontal and occipital headaches. The secondary sex characters may be undeveloped. They are benefited by long continued increasing doses of thyroid. The hyperthyroid type shows its abnormal changes about puberty. They are as a rule tall, thin and highstrung, similar to the adrenal type, often manifest exoph-

thalmos, and show evidences of sympathetic irritation. They blush and perspire freely. Urticaria and other dermatoses are frequent. Migraine, neuritis and active mental disorders are common. Pancreas and thymus gland substance help somewhat. Atropine and quinine hydrobromide are synergistic.

In malnutrition associated with anemia, blood dyscrasias such as purpura, hemophilia and scurvy have been found clinically and experimentally to be due to faulty metabolism, reduced alkalinity of the blood, changes in the viscosity of the blood and disturbances of the hemopoietic organs and lymphatics. Thyroid and the gonads increase the hemoglobin content. Thymus, thyroid and calcium lactate increase coagulation time. The latter is important, for in tonsillar operations the administration of thyroid and calcium lactate for a few days prior to the operation will improve the effect of the anesthetic, diminish operative and postoperative bleeding, and shorten convalescence. This was my experience in many of my cases, as reported to me by Dr. C. N. Gelber, who operated. Iron compounds, arsenical preparations, hemoglobin and lymphatic substance are synergistic. The treatment directed at the anemia is bound to fail unless these fundamental underlying elements are regulated simultaneously.

DIABETES AND ACIDOSIS.

Without a doubt the capacity of the body to burn up sugar is related to the ductless glands. It is known that hypopituitarism causes a marked increase in the tolerance to sugar, and that the adrenals, thyroid and pancreas are definitely related to glycosuria. Acidosis is frequently the cause of death in diabetes. Diabetics have a tendency toward a deficiency of the alkaline reserve and consequently to an excess of acid substances of the disturbed metabolism. Allen contends that feeding fat while withholding carbohydrates is the surest way to induce acidosis in diabetes. Langdon Brown regards diabetes as a product of an exaggerated metabolism evoked through the sympathetic. The thyroid, adrenal and pituitary are all overstimulated but the pancreas is underactive, thus affecting carbohydrate metabolism. In treating diabetes we must counteract the excessive metabolism and increase the internal secretion of the pancreas.

Normal body and mental growth and nutrition are to a certain extent dependent upon a normal set of teeth. The internal secretions have a certain favorable influence upon the dental tissues in bringing about eruption; cause sufficient calcification previous to eruption which is concerned in the prevention of caries through the alkalinity of saliva; arrest decay should caries supervene and, possibly by means of a trophic action, keep the tooth tissue in such healthy condition as to resist caries. In the causation of caries of the teeth, the ductless glandular balance is upset in the direction of calcium hunger. Experimental removal of the thymus caused delay in the development of the teeth, of the thyroid retention of the deciduous teeth. Dyspituitarism gives rise to all sorts of teeth abnormalities as to shape and position of the teeth. I had many cases where small doses of thyroid hastened the eruption of teeth and minimized reflex socalled teething symptoms. Also in skin lesions, we find quite frequently organotherapy effective where all other usual therapeutic measures have failed. A. Z. Hall and Edelman have reported cases of children literally covered with a sticky eczema wherein small doses of thyroid cleared up the condition when all ordinary treatment was of no avail. Aside from the nutritive disorders of children, developmental anomalies and disturbances of growth must also be considered as important and to a certain extent interdependent endocrinologically. The conditions of abnormal growth and development, especially in children requiring special attention, constitute a serious and difficult problem in medicine. Laboratory investigations and clinical experience have shown that disturbances of the internal secretions, particularly the thyroid, pituitary, thymus and gonads, are responsible for the anomalies of growth and morphogenesis. The difficulty in diagnosis, as well as treatment, lies in one's ability to recognize these abnormalities early, when our efforts are more likely to be effective.

In the class of cases of growth dystrophies, many of the stigmata obviously are manifestations of an organic nature and should not be expected to be remedied. But since the underlying element is a disturbed function of some of the endocrine glands, their remarkable responsiveness to hormone stimuli may enable us to bring about some noteworthy organic changes, so that even in these cases organotherapy may assert a definite influence upon structural, as well as functional defects. The differentiation between those defective children that are likely to respond to organotherapy and those in whom there is no likelihood of benefit is very difficult, and it is a serious thing to doom a child to lifelong disability by saying that this or that method of prospective merit need not be used because it is useless. The importance of giving early attention to the defective child cannot therefore be too strongly emphasized.

In discussing the subject of infantilism, there is great difference of opinion as to its etiology and classification. Infantilism has been divided into two main groups: the Brissaud type, or hypothyroid condition, in which the somatic and psychic characteristics are accompanied by the facial and physical signs of thyroid insufficiency; and the Lorraine type miniature men (Meige), a group wherein the subject is of small dimensions. Maranon divides them into endocrine infantilism, i. e., thyroidic, pituitaric, pancreatic, adrenal, hepatic and essential infantilism of gastrointestinal and infectious origin. Bauer considers that in all cases of infantilism the patients are not really sick, but miserable physiological specimens constitutionally weak. Cavengt applied the term patocativism to describe infantilism of either monoglandular or pluriglandular form. Autopsy in many cases of infantilism proved all of them to be of pluriglandular origin. I believe with Cavengt and Chauvet that all cases of infantilism should be diagnosed early from the moment the patient reaches us, and to fix the time of its inception as related to the age which corresponds to the size and weight and other characteristics instead of waiting until puberty for diagnosis. The earlier treatment is applied the greater the improvement and the more rapid the results. The adrenal infantilism of Moriat is occasionally encountered. Herter, in 1908, called our

attention to intestinal infantilism, of which there are two types, the Huebner occurring during the first year, and the Herter occurring in the second year or later. Karrer, Cavengt and L. I. Harris reported such cases. In Dr. Harris's case the patient improved after a blood transfusion. It may have stimulated the individual's hormones to activity as growth from then on was progressive. In most of these cases that came to autopsy, there was found hypoplasia, congestion, degeneration and sclerosis of the various ductless glands, one more affected than the other at the same time.

Another cause of confusion is dwarfism. The essential dwarfs of Chauvet are perfect beings within their height, the numerous somatic atrophies which these subjects suffer not indicating constitutional weakness, as in infantilism. These have a degree of health considering their small size, their functions are normally performed, and their brains are as well developed as normal individuals of their age. Dwarfs are divided into proportionate dwarfs or "adults in small mold;" and do not present normal sexual or osseous development, and disproportionate dwarfs, wherein we find undeveloped members of the body, such as one upper or lower extremity, one side of the face, etc., shorter than the other half, also known as achondroplasia. Parrot, Porak, Marie, Bassoe and the author have described and reported a number of these cases. Thymus gland substance has some influence in these cases when administered early, particularly when associated with pituitary and thyroid extracts. In some of the cases of arrested growth, the subjects become prematurely old, a condition known as progeria. This condition usually begins in youth and little can be done for them.

I shall now consider the other abnormal growth dystrophy known as gigantism and acromegaly. The influence of the pituitary, particularly the hypersecretion of the anterior portion, thyroid, and gonads on gigantism, no matter of what type has been unquestionably demonstrated. The pancreatic function is undoubtedly also altered because of the accompanying glycosuria. When gigantism and acromegaly are combined, the latter is usually preceded by the former. Gigantism begins before epiphyseal lines close or in childhood. Horrax states "that these cases after a while tend eventually to hypofunction of the hypophysis, expressing itself in weakness, hypotrichosis, impotence, adiposity and low body temperature." Such symptoms also indicate hypothyroidism. The symptoms of acromegaly develop slowly over a period of years. In some patients the cerebral and genital symptoms appear years before the skeletal changes are noted, as also the characteristic spacing of the upper central incisors due to enlargement of the superior maxilla. These patients are irritable, bright, distrustful, petulant, indecisive, abusive and unreliable. A Wassermann test should be made in every case because of the frequency with which syphilis is associated with acromegaly. The Froehlich, Burnier and Cushing types include most all the possible dyspituitary syndromes. An amyotrophic form, a painful one associated with gigantism, trophedema, myxedema, and one accompanied by severe nervous and mental symptoms were also described. W. Timme, recently described a pluriglandular compensatory syndrome of thymus pituitary combination beginning in youth some years before puberty and going through four stages in about two decades. The first stage indicates characteristics of the status hypoplasticus of Bartels showing a general hypoplasia of the endocrines with a hyperactive thymus. The second stage shows the gonads beginning to grow active with adrenal insufficiency, and then comes the all important third stage in which the pituitary gland is the critical factor. There is the tendency of the pituitary to become hyperactive or erode the sella or its capsule to compensate for the deficiency as shown in the fourth stage. Long continued and graduated doses of pituitary extract help these patients materially, with favorable prognosis. French authors have also described a thyrogenitopituitary syndrome.

In cases of eunuchoid gigantism the patients usually present the dystrophy of long limbs, small head, female pelvis cushioned with fat, scanty pubic hair and infantile genitalia. Here we have defects of the testicular interstitial glands, hypophyseal disorder and hypothyroidism accounting for the symptoms, outlined above, with skin changes and carious teeth.

In conclusion I wish to emphasize the need of early diagnosis and early treatment. Each patient must be individualized and studied separately. In addition to organotherapy the child's or patient's mode of living must be regulated regarding the hygienic environment, regular hours of sleep, normal bowel function, bodily cleanliness, mental and physical recreation. The food should be plentiful, wholesome, palatable, nutritious and rich in vitamines and calories to meet the necessary individual requirements.

From the viewpoint of diagnosis, symptomatology, pathogenesis and therapeutics in nutritional and growth disorders of children, the ductless glands and their internal secretions play an important rôle in solving many of the formerly unknown problems as to etiology of various syndromes and complexes.

Ovarian Feeding*

By JOHN ROGERS, M.D.,
New York.

Of all the endocrine preparations, those made from the ovary seem to be the most frequently prescribed. The price of the raw glands has risen from a few cents a pound ten years ago until now it is in the neighborhood of five dollars, and any woman who presents obscure symptoms is fortunate if she escapes this rather costly medicament. Nevertheless, there is little or no knowledge of what the active material in the ovary is, whether it lies in the corpus luteum, in the socalled interstitial cells, or in both, or of where or how it produces its effects. Some experiments with extracts of this gland seem to prove that its administration is followed by an increase of pituitary secretion in the spinal fluid and so, apparently, connects the secretory activity of the ovary directly with that of the pituitary gland.

In the Cornell Laboratory, the castration of bitches is followed at the end of three or four months by a great increase in the animals' fat, or a change well recognized in everyday experience, and also by a relatively large increase in the iodine content of the thyroid but without any noticeable change in the size of this organ. So there are some definite reasons for believing that the pituitary, the thyroid and the ovary are functionally related. In the anatomical department at Cornell, it has been demonstrated that the œstrus of the guineapig occurs at regular sixteen day intervals and lasts about twenty-four hours. Ovulation occurs during each heat period, and a "marked correlation exists between the œstrus changes in the uterus and the developmental cycle of the corpora lutea." During this cycle, which represents the maturation and rupture of the graafian follicles and the degeneration of the corpus luteum, there are typically corresponding changes in the vagina, uterus and ovary, and they can all be recognized by microscopical examination of a smear taken from the interior of the animal's vagina (1). Changes in this cycle can be induced and detected by the administration of various glandular extracts, particularly if they are made from the ovary, and the test looks very promising for learning something definite about the physiology and comparative activity upon the genital tract of the component parts of the ovary.

For medicinal use, the most available sources of ovarian supply are the cow, sheep and pig. In our work, the sheep has not been employed. The young cow ovary is about the size of the terminal phalanx of a large thumb, and usually contains one globular corpus luteum some half inch in diameter with a few drops of follicular fluid and one or two other less fully developed globules. These can be readily trimmed away from the rest of the ovary, and are presumably the source of the sterile extract of corpus luteum so commonly employed hypodermatically for the vomiting of pregnancy. Its efficacy is variable or uncertain, and rests upon somewhat doubtful reasoning. The old cow ovary generally contains no gross corpus luteum or graafian follicle, and can be used for determining the effects, if any, of the so-called interstitial cells. The pig's ovary is about half the size of that of the cow, and is covered with a great number of corpora lutea, or graafian follicles, some eighth inch in diameter, and each holds more or less of the follicular fluid.

The tablets, or powder, of ovarian substances, or of corpus luteum, are made by various methods of defatting and desiccation chiefly of these two animals' ovaries, or of the cow's corpora lutea. The defatting process is necessary for the removal of the lipoids which prevent drying and so produce putrefaction. There is, however, a method apparently not yet in commercial use, by which animal tissues can be dried without change except in the removal of water. Aqueous extracts cannot, of course, contain in solution any appreciable amounts of fatty material which many experiments suggest are essential.

Some years ago, in an attempt to surmount these difficulties, in defatting and drying, there was introduced the nucleoprotein substance which was derived chiefly from pig ovaries. This preparation presents some advantages over the common desiccated product, but is not always as efficacious clinically as it should be, and we have, therefore, been seeking others. For extraction purposes, glycerin offers many advantages. It disintegrates cells and takes from a gland its water soluble and most, if not all, of its lipoidal contents, but is not an ideal preservative. This medium, by the way, was the one first used to introduce organotherapy by thyroid feeding.

In some preliminary experiments conducted at Cornell by Dr. Blau, from the Department of Chemistry, in conjunction with Dr. Papanicolaou in the Department of Anatomy, to determine the comparative effects of different derivatives of the ovary upon the guineapig's œstrus cycle, there have been obtained some very suggestive results. All of the defatted, or common commercial desiccated ovarian materials are either uncertain in their effects or inert. Of the extracts of fresh glands, those made with alcohol or glycerin seem the most active, and both of these kinds of extracts contain more or less of the lipoids. Incidentally, the follicular fluid which can be obtained from the graafian follicles of young cow ovaries, though showing some activity, is not as potent as the alcohol or glycerin extracts of the whole corpus luteum or of the whole pig ovary. So far as the experiments now indicate, the glycerin extract, especially if a little defibrinated beef blood is added during the period of its extraction, is apparently the best. If it contains material from the corpora lutea, it seems to induce promptly and to prolong the phenomena of the guineapig's œstrus, whereas if these bodies are excluded the œstrus is apparently postponed and some very curious late results supervene. In other words, the interstitial cells, or their secretion, seem to have some specific retarding effect upon menstruation which differs from that of the graafian follicle and its corpus luteum. Strangely enough, the feeding *by mouth* to oophorec-

*From the Livingston fund for Experimental Therapeutics and Biochemistry in the Cornell University Medical College.

tomized pigs of a glycerin extract of pig ovaries which contain in abundance all of this organ's elements, seems to induce at least a pseudoœstrus. This may be a valuable hint in the treatment of many neuroses of the natural or artificially induced menopause. But as yet the experiments with ovarian materials are not far enough advanced to draw any definite conclusions. It is enough to state that there are now at least promises of physiological tests which seem capable of clearly demonstrating the comparative activity of ovarian derivatives and the location in which they manifest their chief effect. In the absence of such criteria, the common practice of ovarian feeding rests upon very insecure foundations. If the ovary produces a secretion which influences the metabolism of other organs, as there is no doubt it does, we have practically no knowledge of its character nor mode of action, but every step in the elucidation of these problems is of great interest. So far as our experiments indicate, it is reasonable to believe that at least some of the active material is associated with the ovarian lipoids in the corpora lutea, and that this material is capable of producing effects after passage through the digestive tract and so should favorably influence the deficiency disturbances in women which occur at the menopause. It is also possible to infer that it might bring on the menstrual flow in some forms of functional amenorrhœa. For apparently the ingestion of an animal's corpus luteum, with its lipoids, supplies something which either stimulates the development of this organ in the patient, or else takes the place of what it should produce.

In purely functional dysmenorrhœa it is conceivable that the pain has a mechanical origin, which means that it is due to congestion and consequent pressure in an attempt to supply to the ovary some lacking nutriment, and that ovarian feeding provides this specific nutriment. Clinically, the oral administration by mouth of the glycerin extract of the pig ovary rather than any other preparation seems in this particular neurosis most useful.

In functional menorrhagia, or metrorrhagia, entire ovarian extracts should, according to results obtained upon the guineapigs' œstrus, be contraindicated. For any material containing derivatives of the corpus luteum seems to induce and prolong the œstrus and ought to have the same influence upon the human equivalent. If any ovarian products are administered for excessive menstruation, those in which there is an admixture of corpus luteum should, theoretically, be excluded. The treatment by this form of organotherapy of the almost countless neuroses or disorders of nutrition without demonstrable organic lesions, and I regret to say of many diseases which have no known relationship to the ovary, is only justifiable by its harmlessness. Nevertheless, it should be noted that not infrequently excessive or prolonged ovarian feeding may induce an acute and sometimes febrile disturbance with nausea and vomiting, and occasionally a palpable enlargement of the liver. At present the only definite symptoms for which there is reasonable prospect of relief by "ovarian feeding" are:

1. The hot flashes of the natural or artificially induced menopause, and sometimes the accompanying high blood pressure.
2. The pains of purely functional dysmenorrhœa.
3. An occasional functional amenorrhœa, if the medicament contains derivatives of the corpus luteum.

In all other disturbances known or supposed to originate in the female genitals, little or nothing is known about the effects of this form of treatment. The best form in which the ovarian material can now be administered seems to be a glycerin extract of the fresh pig ovary.

Exophthalmic Goitre Without Exophthalmos and Goitre*

By ISRAEL BRAM, M.D.,
Philadelphia,
Instructor in Clinical Medicine, Jefferson Medical College.

Depending upon the presence or absence of bulging eyes and large neck, the diagnosis of exophthalmic goitre may be either an extremely simple or an extremely difficult task. Because of the questionable presence, late occurrence, or total absence of eye and neck signs in a large percentage of sufferers from this syndrome, such diagnoses as early phthisis, diabetes mellitus, paroxysmal tachycardia, nervous indigestion, neurasthenia, and occasionally, during a crisis, acute appendicitis, gallbladder disease, or insanity, are resorted to. The main causes of error in the diagnosis of atypical goitre are two: First, the elusiveness of the symptomatology in a large percentage of instances, and second, the term exophthalmic goitre itself.

*Read at a meeting of the Philadelphia County Medical Society, October 10, 1923.

The more intensely one studies this syndrome the more one realizes that a swollen thyroid and bulging eyes are not essential to its diagnosis. Rather than accept the usual definition in which exophthalmos and goitre are depended upon as two of the four cardinal symptoms, it would seem that the following definition would be far less misleading: Graves's disease (Basedow's disease, Parry's disease, Flajani's disease) is a chronic, rarely acute affection, apparently due to a dysfunction of the endocrine organs and of the vegetative nervous system, characterized by increased catabolism, afebrile heart hurry, emotional disturbances, tremor, dermographia, weakness, loss in weight, and usually also by a varying degree of exophthalmos and thyroid hyperplasia.

In approximately twenty per cent. of instances the

thyroid is never appreciably enlarged, and in about fifteen per cent. the eyes never protrude in otherwise typically outspoken Graves's disease. The percentage of cases without exophthalmos and without goitre is apparently much greater if we take into account the instances in which these signs occur late in the affection. Is it not evident, then, that the term exophthalmic goitre is misleading and should be relegated to the list of obsolete terms? For want of a better name let us rather adhere to the term Graves's disease to designate this widespread affection,—a disease which should be removed from the classification of goitre and placed in the category of constitutional affections. This, more than any other procedure, would assist in keeping the busy practitioner's mind open in difficult cases and thus reduce the number of errors committed.

From a study of a large series of cases I find that the most constant evidences of active Graves's syndrome are:

1. A basal metabolism of over plus fifteen.
2. Afebrile heart hurry[1] of over 90 a minute, not materially reduced by sleep or by the administration of digitalis and allied drugs.
3. Emotional disturbances with a reduction of the threshold of emotional response and a quickening of mental activity.
4. Fine tremor of the outstretched fingers.
5. Dermographia and a varying degree of hyperidrosis.[1]
6. A relative immunity to cinchonism (in approximately ninety-seven per cent. of cases).

These clinical factors are sufficient for an accurate diagnosis, existing in combination in all active cases of Graves's disease and coexisting in no other affection.

Why does one patient present exophthalmos, goitre, or both, and why is it that in another there is an absence of one or both of these signs? The consensus of opinion regards exophthalmos in Graves's disease as due to stimulation of the cervical sympathetic. If this be true, it is reasonable to assume that the absence of exophthalmos is due to an insufficiency or absence of stimulation of the responsible ganglion. Moreover, in a considerable percentage of cases the presence or absence of exophthalmos depends upon the personal equation, and what may be regarded by one clinician as slight exophthalmos, may be ignored by another. Even the exophthalmometer is of no practical assistance in borderline instances. Incidentally, we must not ignore the small percentage of cases in which but one eye tends toward exophthalmos while the other is normal, and the fact that irrespective of the existence of exophthalmos, a larval or outspoken von Graefe's sign is elicited.

The absence of thyroid enlargement in a given patient may be explained on the ground that an organ need not become enlarged in order to enter into a state of dysfunction or even hyperfunction. This, however, must be stated of the thyroid in cases without evident goitre: Even in instances of apparently normal thyroid on inspection. there is usually a definite enlargement on palpation, and on auscultation the typical bruit may be elicited. Here, too, the personal equation of the diagnostician is a factor, for the term goitre is an elastic one, and in doubtful cases what is a goitrous thyroid to one clinician may be regarded as a normal organ by another. Again, we must not ignore the instances of apparently absent goitre in which hyperplastic thyroid structures exist retrosternally or in relation with the tongue, pharynx, ovaries, and elsewhere.

In patients without apparent exophthalmos and thyroid swelling the appearance of fright is absent; instead there is an expression of anxiety or helplessness. The pulse is less labile and hypotension is less likely to occur. In other respects the clinical picture in these cases is similar to that of typical Graves's disease.

Untreated, in such patients either exophthalmos, large neck, or both may develop, or the usual course without neck and eye symptoms may occur. Properly treated, the course of the affection is usually arrested, the favorable progress eliminating among other things the possibility of occurrence of exophthalmos and goitre.

If it be true that typical Graves's disease responds satisfactorily to nonoperative measures, how much more likely is it that patients unhampered physically and mentally by distressing exophthalmos and goitre recover health, happiness, and usefulness, without the knife. Indeed, such patients may be discharged from nonoperative treatment a few months sooner than those with socalled typical Graves's disease.

In view of the still existing differences of opinion in many quarters regarding the management of Graves's disease, the mention of the following guiding principles in the nonoperative treatment is timely:

1. An earnest attempt must be made to ferret out and remove all discoverable etiological factors, whether intrinsic or extrinsic. Though I believe too much emphasis is placed upon infectious foci in the pathogenesis of this disease, these, of course, must always be corrected. I find that in many patients there exists a dominating psychological or sociological error urgently calling for adjustment.
2. Rest in bed is important, but unless serious cardiac lesions exist, a complete stay in bed rests neither body nor mind. A respite from bed of at least three hours morning and afternoon is highly desirable in the average patient.
3. Briefly stated, the diet must be of nonflesh quality and of ample quantity. As a rule a sufferer from Graves's disease should be urged to consume twice as much food as is taken under normal conditions. The gastrointestinal difficulties frequently encountered must be promptly overcome by all means at our disposal, for a good digestion is a most useful ally in this disease.
4. Drugs may be employed only after careful individualization. There is no specific drug for this disease, and even quinine, though harmless, is found useless in some patients. Circulatory, nervous, gastrointestinal, renal, and other symptoms must be managed according to indications, as viewed through the medium of experience. The quinine salts, corpus luteum, posterior pituitary, suprarenal cortex, arsenic, luminal, and the iodides in small doses are a few of the substances which have their field of

[1]The heart rate may be normal or below normal, and the skin may be dry in those instances in which there is a combination of inactive Graves's disease with hypothyroidism or in cases of exhausted or so-called "burned out" thyroid with signs of myxedema. These are not active cases of Graves's disease as above designated.

usefulness. On the other hand, it is of utmost importance to know what not to give; in this category are included such substances as thyroid extract, suprarenal medulla, the opiates, the iodides in large doses, and digitalis. However, digitalis may be employed in a still persisting heart hurry during convalescence.

5. Electricity, occasionally useful, is not a mainstay, but at best a supplement to other appropriate measures. Here, too, careful individualization must be exercised.

6. Psychotherapy in Graves's disease is of utmost importance. These patients have been lacking in mental tranquillity for a long time, and this lack is frequently an etiological factor. If psychic harmony be procured, the most stubborn obstacle to recovery is removed. The doctor himself plays his part in the achievement of the necessary mental adjustment. A grave attitude in Graves's disease is inimical to success. In patients who still possess recuperative powers, who are not insane, and in whom unequivocal cooperation in treatment is obtainable, the properly equipped internist is capable of effecting complete recovery within from six to eighteen months.

CONCLUSIONS

1. Increased basal metabolism, afebrile heart hurry, emotionalism, tremor, dermographia, and relative immunity to cinchonism are the most reliable evidences of active Graves's disease.

2. Since exophthalmos and goitre are not essential to the diagnosis of Graves's disease, the term exophthalmic goitre is misleading and should be discarded.

3. Patients without exophthalmos and goitre do not present the physiognomy of frozen fright, and recover more promptly under treatment than those presenting these signs.

4. Graves's disease is curable by nonsurgical means.

1633 SPRUCE STREET.

The Endocrinological Aspect of Dermatology*

By SAMUEL FELDMAN, M.D.,
New York,
Adjunct Attending and Chief of Clinic Bronx and Lebanon Hospitals, Department of Dermatology and Syphilis.

In the pathogenesis of dermatological conditions there are numerous indications that many of them are due to disturbances within the system. Even the reaction of the skin to external irritants is dependent upon changes within the system. For example, chromophytosis can only be grafted upon a skin that has a special susceptibility for it. Blastomycosis is more common in patients with high blood sugar. There is an individual susceptibility to poison ivy as well as to dermatitis from other causes. These changes are both nutritional and metabolic, chemical changes within the system and endocrine disturbances.

The popular belief that overfeeding with acids and condiments has something to do with causing certain diseases of the skin is clinically correct. It causes a disturbance of calcium metabolism and hyperacidity. The latter is known to be responsible for rosacea and herpes labialis. A diminution of the calcium content of the blood has been found to be a nearly constant accompaniment of a certain group of leg ulcers. As the parathyroids have been held responsible for the regulation of calcium metabolism, attempts have been made to treat these cases with extracts of the latter glands. The results were more than gratifying. It is interesting to note that feeding these patients with calcium salts has no influence upon the course of the disease.

Pruritus and eczema may accompany diabetes and nephritis or there may be evidence of a disturbance in kidney function without apparent kidney lesions. This will show itself in an increased chloride content and in nitrogen retention. The lesions in diabetes are most frequently located in the region of the genitals and the anus. They readily respond to diabetic diet and to insulin medication. In some of the above mentioned diseases, as well as in urticaria, uricemia is found. This disturbance in purin metabolism appears, according to the hypothesis of Abel and supported by many investigators in metabolism, to have a relation to the vegetative nervous system. These cases respond to combined atropine and cinchophen treatment. Other cases of eczema, pruritus, and urticaria are dependent upon vagotonus. They occur in patients with symptoms of the socalled vagotonic syndrome, such as asthma, hay fever, chronic conjunctivitis, and bradycardia. Hyperglycemia is usually present. The lesions, as well as the hyperglycemia, clear up under atropine. Certain eczemas occur in either the very thin or the very fat individual. In the adipose, the condition may depend upon either the thyroid or the pituitary. They can be differentiated by calculating the combustion coefficient. While basal metabolism is increased in hyperthyroidism and diminished in hypothyroidism, it remains within normal limits in pituitary dysfunction. Many of these cases are due to protein anaphylaxis. The manner in which the latter is linked with the endocrines is as yet not well understood. The instantaneous response of the exudative lesions, as well as attacks of asthma, to adrenalin injections easily links it with the vegetative nervous system.

There are numerous other dermatoses which are frequently found in patients with endocrine disturbances and are favorably influenced by treatment with extracts of the various glands. Even psoriasis has been successfully treated with stimulating doses of x rays applied to the thymus gland. Usually, a week after the first application, the lesions begin to

*Read at a meeting of the Section in Internal Medicine of the Bronx County Medical Society, November 19, 1923.

itch. This is supposed to be due to freshly secreted thymic hormone. Gavalefsky (1) claims success in sixty-five per cent. of his cases so treated. I have seen good results from this method of treatment both in Zumbusch's clinic at Munich and in my own practice. However, I have also seen recurrences after it.

There is justification in the general belief that dermatoses may be due to disturbances of puberty and the sex organs. Itching of the skin is given as a first sign of pregnancy. Itching of the genitals at various periods of life is known to all. So are the eruptions occurring during the life changes and their disappearance with the establishment of puberty. Even purely exogenous dermatoses may occur at certain periods of life and disappear under certain variations in the economy of the individual. Microsporon always heals sponaneously with the establishment of puberty.

Acne invariably begins with the onset of puberty and, with very few exceptions, disappears with its termination. There are characteristic hair changes in this condition. In the male, the beard is scant, the facial appearance often resembling castration eunuchoidism. In the female, on the other hand, there is a luxuriant growth of hair, often amounting to an actual beard. There is no basis for the belief that this disease is due to sexual abstinence. In acne, the latter is due to a diminished sexual appetite which usually accompanies it.

The three symptoms enumerated above—the appearance of the disease at puberty, the hair changes, and the diminished sex appetite—are dependent upon the gonads and their regulating glands, the thymus, the pituitary, and the thyroid. The extreme frequency of hyperglycemia in pustular acne also points to an endocrine origin of this condition. In spite of all that was said, not all cases of acne respond to endocrine treatment. The greatest enthusiasts (2) report less than fifty per cent. cures. I must confess that I was not as fortunate in my cases and had to resort to x ray treatment to clear up the lesions. This, however, is followed by endocrine treatment, whenever it seems indicated, with the hope of preventing recurrences. Pick (2) reports an interesting case in a patient with a bad acne in whom the disease completely disappeared after marriage at the age of twenty-six only to reappear when he became a widower at thirty-eight. This would make it appear that abstinence may be an influencing factor in the causation of acne.

The skin symptoms of gonadal dysfunction are as follows: There is a very fine infantile skin in the male and an atrophy from lowered activity of the glands in old age. It causes a thinning of the hair in the male and hypertrichosis in the female. The same occurs in a more marked degree after surgical removal. Most of the cases of hypertrichosis occur in unmarried women. It would appear that normal sexual life inhibits this condition. In one hundred and forty-six cases reported by Bechet (3), one hundred and thirty-one patients had more or less severe menstrual disturbances. In hypertrichosis, the ovaries do not act alone, there is a correlation between them and the pituitary, pineal, and the suprarenals. This is true of most of the conditions due to endocrine dysfunction.

Dermatitis dysmenorrheica symmetrica is a distinctly bilateral and symmetrical disease occuring only in women with complete amenorrhea, in those with a very scanty flow, and when the intervals are unduly prolonged. It is usually associated with hysteria. It is caused by a decomposition of ovarian protein within the ovary. This is demonstrated by a positive Abderhalden reaction for ovarian protein. The circulation in the blood of a certain lipoidal toxin is caused thereby. The latter can be demonstrated by the method of Hermann and Neuman (4). It is constantly found in the pregnant, after castration, in the climacterium, also in women with badly functioning ovaries. Polland (5) and other observers found this lipoid in all their cases of dermatitis dysmenorrheica. Geber (6) sensitized patients with the blood from women with that eruption and then injected blood from menstruating women and caused the disease to appear, proving the presence of a toxic substance in the blood of the latter. Dermatitis gravidarum, a disease which so often taxes the wits of the gynecologist, has the same origin and pathology, namely, urticaria with necrosis. These cases are very favorably influenced by treatment with ovarian extract. Kreibich (7) reports two interesting cases. One in a girl who manifested the disease at the age of ten and had complete amenorrhea at twenty-two. The other case was in a man in whom the disease developed after castration.

There is a comparatively large group of pathological changes in the skin which are known to be due to thyroid dysfunction. Those found in hyperfunction are marked hyperhydrosis, especially of the axillæ, transient erythemas, urticaria, prurigo, pruritus, melanosis, chronic alopecia, hyperkeratosis, and dystrophy of the nails. In hypothyroidism, there is a falling of the hair or it may remain sparse and undeveloped. I have two cases on record of total alopecia in children with mild symptoms of cretinism, in which the alopecia was cured in the course of several weeks by small doses of thyroid extract. One case occurred in an Italian girl of fifteen who as yet had not menstruated and presented mild symptoms of cretinism. The alopecia disappeared rapidly under treatment with thyroid, pituitary, and ovarian extract. She was completely amenorrheic, however, three years later in spite of continued treatment.

In myxedema, the clinically swollen skin is due to profound pathological changes. The cutis is atrophied, the elastic fibres are swollen, the collagenous bundles become attenuated and almost disappear. Both these structures become converted into an homogeneous mass, similar to the substance found in the thyroid. There is an obliterating endarteritis and occlusion of the lumen of the glands.

A number of cases of skin dystrophy and atrophy are apparently due to improperly functioning thyroids. Some of the socalled idiopathic atrophies, cutis verticis gyrata, ichthyosis and ichthyosis hystrix have occasionally been found in patients with thyroid dysfunction and have been benefitted by thyroid therapy. Lipodystrophia progressiva, in which the fat from the subcutaneous tissue of the upper part of the body completely disappears, the process end-

ing at the crest of the illium, and Dercum's disease, with its accompanying ulcerations, and occasional bullæ and other trophic disturbances of the skin, belong in this group. While Price (9) found pathological changes in the thyroid in five out of six cases of the latter disease, other observers believe that the fault lies in pituitary dysfunction. In scleroderma, there is an atrophy of the papillæ, a conversion of both the elastic tissue and the collagen into an homogeneous hyaline mass and an accompanying obliterating endarteritis. This disease is recognized to be due to thyroid dysfunction.

Gerson (10) found a vagotonia in all of his cases. As he found no means of reducing it, he attempted to raise the sympathetic tone in order to produce equalization. In this manner, he asserts that he has cured all his cases in a few months. Many reports of cures of scleroderma with thyroid extract are on record. The opposite conditions prevail in multiple neurotic gangrene of the skin. This disease starts with an area of hyperesthesia. This soon becomes red, a wheal like eminence develops, and a mild necrosis occurs in the centre. In most of these cases, pronounced symptoms of hyperthyroidism are present. The presence of sympathicotonus is constant and frequently there is hysteria associated with it. Sclarz (11) cured several cases of this disease with antithyroidin. Some cases were cured by pilocarpine. The object in giving this drug was to raise the tone of the vagus to equalize the sympathetic hypertonus. Pavlovic (12) reports two cases of ichthyosis cured in the same manner.

In hyperpituitarism there is hypertrichosis, an increased size of the hair follicles, and an enlargement and activation of the secretory glands causing a moist and greasy skin. There is an hypertrophy of the papillæ, an increased prominence of the furrows of the hands and feet, and an increase of the connective tissue of the subcutis, giving the skin a dense and boggy feel. In hypopituitarism there is a thinning of the hair of the scalp in the adult. It becomes dry and strawlike. There is falling of the axillary and pubic hair and there is a feminine distribution of the latter in the male. The skin is smooth and transparent, almost infantile in character. It is dry and deficient in perspiration. Dystrophia adiposogenitalis presents many of the symptoms mentioned above and is a disease due to pituitary hypofunction. Several cases of Raynaud's disease were successfully treated with pituitary extract and cases of Recklinghausen's disease associated with hypopituitarism and acromegaly are on record. In the latter disease, hyperpigmentation is frequently present. There are cases on record of that disease occurring in patients with hypoadrenia and tuberculosis of the adrenals.

The most important cutaneous expression of suprarenal hypofunction is pigmentation. In Addison's disease it is usually a later manifestation, although it sometimes precedes all other symptoms. In a case reported by Greenow (13) it preceded the disease by eight years. It is most marked in the areas that are normally pigmented, notably the areolas of the nipples, the scrotum, groin, extensor surfaces of the forearms, and the axillæ; also in the exposed regions, as for example the face, neck, and back of the hands. It is found on the mucous membrane of the tongue, inner surfaces of the cheeks, and on the gums. It is usually absent on the palms and soles. The pigmented patches are diffuse, without any sharp margin. Occasionally, however, small molelike patches and specks, as black as ink, are scattered all over the body.

Adrenotropism or melanotropism is a condition in which there is pigmentation similar to that present in Addison's disease, but without any other symptoms of hypoadrenia. The hair is coarse and inelastic and is very poor in natural oil. Its color is usually darker than is usual with the nationality to which the patient belongs. In Addison's disease, the hair occasionally turns black. Hyperpigmentation in chloasma, acanthosis nigricans, and perhaps also in secondary lues may be due to the same cause, namely adrenal insufficiency. The same may be said about the pigmentation which accompanies tuberculosis.

THEORY OF PIGMENT FORMATION.

There is an increase in physiological pigmentation due to the influence of a faulty sympathetic nervous system. This theory holds that the pigmentary changes are not due to the adrenals themselves, but to lesions or an irritation of the pericapsular nerve apparatus which presides over the pigment function. The presence of a similar melanoderma in patients with tuberculosis, especially of the peritoneum or the intestines seems to speak for it. There is an increased number of chromatophores and melanoblasts in the skin. The latter cells are supposed to be under the influence of the sympathetic nervous system. The reason for this belief is that during early embryonic life, these cells are supposed to be wandering neuroblasts. Some of them go to form the sympathetic ganglia and the visceral sympathetics. Others do not develop into nerve cells, but retain their original form and present a peculiar affinity for chromic acid. Hence they are called chromaffin cells. They are supposed to be identical with the chromaffin cells of the adrenals. There are no chromoblasts in the cutis. The pigment cells in the latter location are chromatophores or pigment carriers. Miescher (14) believes that these cells are ordinary fibroblasts which have taken up pigment derived from the cells of the epidermis. The latter give up their pigment when it is excessively formed or when pathological changes take place within the cells. For that reason, chromatophores are abundantly present in the cutis in the region of a patch of vitiligo. Miescher was able to prove experimentally that connective tissue cells have the power of absorbing substances from the tissue fluids and store them. He was able to produce artificially chromatophores by injecting melanin into the skin. As a further proof that the pigment cells of the cutis are not melanoblasts or pigment builders can be mentioned the fact that they do not contain any oxydase. This was sufficiently demonstrated by Bloch (15), who found a negative Dopaoxydase reaction in the cutis in all of a large number of specimens examined.

Side by side with the pigment in the epithelial cells of the skin, there is another substance from which the pigment is formed. Both these substances have the power of reducing silver nitrate. The invisible prepigmentary substance can be demonstrated as it assumes a dark brown color, the same as mela-

nin. Some hold that this substance is derived from tyrosin and allied substances which are derived from the decomposition of proteins and are precursors of adrenalin. In Addison's disease, adrenalin is not sufficiently formed. The above mentioned substances accumulate in the tissues and in the skin, and are converted by oxydase into a dark pigment belonging to the melanin group. Oxydase can be demonstrated in the basal layer and in the lower two layers of the stratum Malpighii by a process known as Bloch's Dopa reaction. When a piece of skin is kept in a solution of dioxyphenylalanin for a certain length of time, the cells containing oxydase turn a uniform black. This reaction differs from the silver nitrate reaction in that that in the latter the color is brown and is confined to the pigmentary and prepigmentary granules. On staining with dioxyphenylalanin, a number of cells in the basal layer are seen to possess tendril like projections. These are the melanoblasts.

The skin is capable of taking up some of the work of the adrenals. This is evident from the fact that extracts made from skin substance, when injected into the blood is capable of raising the blood pressure. The same happens when the skin is exposed to ultraviolet light. The latter rays do not penetrate beyond the uppermost layers of the skin and, therefore, it is likely that this action is primarily a local one, on the skin structures themselves. When the adrenals are exhausted, there is a great overactivity of the skin. This also causes melanosis.

Vitiligo is frequently associated with Addison's disease, also with Recklinghausen's disease and very often with alopecia areata. The fact that vitiligo and alopecia areata so often go together brings to one's mind the question whether absence of oxydase has not anything to do with causing both of these conditions. Such a viewpoint is strengthened by the fact that the rays from the quartz mercury lamp, so effective in alopecia areata, also stimulate oxydase formation. The latter substance is completely absent in a patch of vitiligo. Both of these diseases are frequent in patients with hyperthyroidism and after the removal of the ovary. Arton (16) cured a number of cases of vitiligo by injecting large doses of ovarian extract. Bearing in mind the helplessness of the dermatologists in this group of cases, the reported cures with endocrine treatment appears significant.

Alopecia, after influenza and other febrile conditions, is supposed to be due to adrenal exhaustion which is always present. The marked sympathetic irritability and the vasomotor disturbances accompanying hypoadrenia causes a disturbance in the nutrition of the hair roots. Good results have been obtained in these cases from treatment with adrenalin and atropin.

Chatellier (17) cured a case of erythromelalgia with adrenalin injections. He believes that it is due to a vasomotor neurosis of endocrine origin.

Patients with diabetes are susceptible to pruritus and eczematous dermatoses, especially of the genital and anal region, also various erythemas, seborrheal dermatitis, furuncles, carbuncles, and other pustular dermatoses. These conditions also occur in all other diseases in which there is a high blood sugar. Other skin conditions frequently found in diabetics are xeroderma, bronzing and gangrene. Xanthoma tuberosum is a disease in which yellowish tumors appear in the skin. These are caused by an infiltration of the cells of the cutis with cholesterin. There is a constant cholestrinemia present. It is very frequently associated with diabetes (xanthoma diabeticorum) and is due to a disturbance of metabolism due to dysfunction of the pancreas. Engman and Weiss (18) cured a case of xantoma diabeticorum with insulin injection. This would make it appear that the latter substance is not simply a sugar burner, as it is taught by some, but has a complex function.

In conclusion, many other dermatoses could be mentioned which are frequently found in patients with endocrine disturbances and are occasionally benefitted by endocrine treatment. The subject of the correlation of the endocrine glands, however, is at present but little understood. While the identical pathological skin condition is found in patients with disturbances of various and even opposing groups of glands, diverse skin conditions are found in disturbances of apparently a single gland. This, however, is true of the entire field of dermatology. Various etiological factors may produce lesions of identical pathology, while numerous and diversified pathological changes may be brought about by a single etiologic factor.

The author's references will appear in his reprints.

Acromegaly Associated with Adrenal Tumor

By HERBERT W. LONG, M.D.,
and JOHN W. GRAY, M.D.,
Newark, N. J.

Case.—The patient was under observation at St. Michael's Hospital six months before he died. He was forty-five years of age and had suffered from pain in the feet and hands about four months. On admission, the hands, forearms, feet and legs were swollen. They increased progressively in size, became pigmented and boggy; and the skin became thickened, wrinkled and dry. The diagnosis of acromegaly was apparent. Signs of lung tumors were not present on admission, only scattered râles over the posterior chest; but signs of consolidation finally developed in the left posterior and right anterior chest. The x ray showed tumors of these parts and also a generalized osteitis and periosteitis with a large amount of new bone formation in the bones of the skull, tibia, etc. The temperature ranged from 96° to 101°, being subnormal several days before death. The pulse rate was 60 to 80. The urine, sputum and blood were negative except for a progressive anemia. Two weeks before death, the

FIG. 1. — Photograph of patient showing enlargement and pigmentation of hands and legs.

hemoglobin was sixty per cent. and the erythrocytes numbered 3,400,000.

At autopsy, the skull was thickened, the frontal sinuses were greatly enlarged, the sella turcica measured five by eleven by eighteen mm. (normal) and the pituitary showed no gross lesions. A degenerated tumor replaced the lower left lobe of the lungs and a smaller tumor involved the right lower lobe. The spleen weighed 410 gm.; the liver 1900 gm.; the right kidney, 210 gm.; and the left, 240 gm. A tumor, forty gm. in weight, involved the left suprarenal; and a large hemorrhagic degenerated tumor weighing 1,000 gm. replaced the right suprarenal. The periosteal shell of the tibia was six mm. in thickness.

Microscopically, the right adrenal tumor was chiefly necrotic and hemorrhagic, but with neoplastic tissue sufficient for diagnosis. The cells of this and of the left adrenal growth varied in size and shape with many giant cells and mitotic forms. There were many undifferentiated ovoid or polyhedral cells with large hyperchromatic nuclei; and also some cells with a large amount of clear cytoplasm, as seen in hypernephroma, which characterized these as adrenal tumors. The lung tumors were more typically adrenal than those of the suprarenals, practically all of the cells here showing a large amount of clear cytoplasm. These new growths were metastases from the adrenal tumors by way of the renal vein, vena cava, right heart and pulmonary artery. The spleen, more than twice the normal size, was fibrous, representing a part of the general

visceral hypertrophy of acromegaly. Bone sections showed a productive osteitis and periosteitis. The pituitary, though not grossly enlarged and symmetrical, showed definite pathological changes in the glandular portion. The normal gland contains two main classes of cells: chromophile and chromophobe. The chromophile cells are either acidophile or basophile. There was in this pituitary an overgrowth of both eosinophilic and chromophobic epithelial cells, the former predominating and forming solid cords and compact groups of atypical epithelium without mitosis. Cords invaded the pars nervosa. Acini filled with colloid substance were present, derived from the pars intermedia.

FIG. 3.—Microphotograph of the lung tumor. The large amount of clear cytoplasm shown in these cells indicate its adrenal origin.

Whether this growth of the pituitary causing acromegaly was the result of deficient adrenal secretion from tumor formation there, or whether the growth in the pituitary caused adrenal hypertrophy with resultant carcinomatous change, is not clear. Rare cases of adrenal hyperplasia reaching an almost adenomatous grade have been reported complicating acromegaly. On the other hand, hyperplasia of the pituitary is normally associated with pregnancy as a result of deficient ovarian secretion, and cases of tumor and acromegaly have been reported following repeated frequent pregnancy. It is also possible that deficient adrenal secretion might have upset the polyglandular equilibrium, and thus produced the pituitary change. Therefore, even though no positive etiological deductions can be made from the report of this case, it shows that the relation of the suprarenals to acromegaly in their relation to the pituitary deserves further study.

Historical Medicine

A Note on Dr. Maynwaringe's Idea of the Infectivity of Phthisis in 1673

By G. ARBOUR STEPHENS, M. D.,
Swansea, Wales,
Consulting Cardiologist King Edward VII, Welsh National Memorial Assn.

The period following the discovery of the circulation of the blood by Harvey seems to have been a time of great mental, as well as of physical and governmental activity. It was in the latter half of the seventeenth century that the Royal Society was established by the Hon. Robert Boyle with a large number of medical men. The discovery of the circulation of the blood, like all great discoveries, had a marked effect on all the great thinkers of that period, inducing some nonmedical men like Boyle and Christopher Wren, to take an active interest in such matters as the transfusion of blood and the injecting of medicated liquors into the veins.

Much of the medical writing of that period is of very great interest and well worthy of being perused even for socalled fresh or modern ideas. A few months ago I drew attention in *Nature* to the fact that the sinoauricular node and fibrillation had both been discussed in 1648 on the strength of some interesting vivisection experiments on the dog by Johannes Walæus, professor of medicine at Leyden University.

Walæus's work was published in the form of two epistles constituting an appendix to Bartholini's *Anatomy,* published in 1650. A few years later a very interesting book was published by E. Maynwaringe, Doctor in Physick, on *The History and Mystery of the Venereal Lues or French Disease,* and in it is a reference to tubercle, which is as follows:

"And as for *phthisis,* why that should be infectious to the lungs of another, there is good reason for it; because the corrupt breath going out of the phthisical person is drawn and received by another (in their near approaches) and coming into the *aspera arteria* of the sound person, is by that canale immediately conveighed through various ramifications into the whole *parenchyma* of the lungs, which being totally pervious, and of a spongious substance, is very susceptible and obnoxious to alterations from the quality of the inspired air."

"And having imbibed *phthisical* corruptive *miasms* in the breath may lodge and fix there, changing the natural tone of the lungs into a *tabid* and *corruptive* state.

"In the next place we are to consider what these miasms or infectious seminaries are that pass from body to body. Some give them the denomination of *vapour,* others a *spirit,* from their subtility and penetration, not that they are void of *corporiety;* but we shall not trouble ourselves upon the name, provided we rightly know what is meant thereby. We are therefore to understand them as *corpuscles* or subtile invisible bodies which are minute small portions exhaling from infected bodies of the same nature and taint, as the bodies from which they are emitted. These venemous *particles* of contagious matter are agile and penetrating, so that they insinuate themselves through the pores of other bodies; and being entered do there ferment and operate to alter and change their new receptacles and tincture them with the like *tabes* of their own virulent nature."

The lines quoted above were written two hundred and fifty years ago and, considering the clearness of thought expressed by Maynwaringe, it is very remarkable that so little progress of a fundamental nature has been recorded since then.

Even at that time there were evidently a large number of nonreasoning members of the profession for he tells us that "Physicians have laboured to find out rational ways of cure, answering their several opinions and determinations of this lues. Empericks, not being capacitated to dive into the abstrusity of this disease, nor willing to spend time about the *notional* part wherein they find no *gain,* fall presently upon the *practice,* consulting only or rather at a venture, *borrowing* from tradition a method of cure which boldly they experiment upon all persons, and whether it hit or miss, are not able to give an account or reason for either."

To what extent have we advanced today? "But," as Maynwaringe states in conclusion, *"populus vult decipi,* they love the imposture, they will not be informed, so let it go on."

61 Waller Road.

The First Scientific Work on Spectacles.—Dr. Casey A. Wood (*Annals of Medical History,* June, 1921), says that this small octavo volume by Benito Daca de Valdez was published at Seville in 1623. It is an extremely rare work, only ten known copies being in existence—one in the library of the Surgeon General in Washington, one in the British Museum, and the remaining eight in Spain. The title page tells us that the subject of the book is the use of spectacles for every kind of sight, with lessons on the varieties of visual defects for those needing a special kind of spectacles. It indicates the time of life when certain lenses are most useful, how these may be prescribed, and discusses other ways of preserving eyesight.

The author was a notary of the Holy Office (Inquisition) in Seville, and he dedicates his work to our Lady of the Holy Fountain of the City of Cordova, about whose appearance in Cordova a friend of the writer contributes a prefatory poetic "romance." The manuscript was censored and approved by the Church, and the published work censored and approved by the State, by which the book was licensed for ten years. The price was

fixed by the State at what corresponds to about thirty cents. "This seems a fair price when one considers that the purchasing power of early seventeenth century Spanish money was about ten times that of present day currency."

The book proper begins with the dedication to the Benign Virgin, followed by an introduction, then comes the romance, then another introduction, and finally the body of the work, divided into three books, the first and second dealing with the anatomy of the eye and the physiology of eyesight, and the last consisting of four curious and interesting dialogues between teachers and pupils on practically the whole subject of physiological optics as it was known at that time.

One chapter of Book I deals with imperfect vision due to congenital and acquired conditions, another describes the great benefits of properly fitting glasses. There are treatises on the socalled depraved eyesight of old age, shortsightedness in infants, acquired poor vision and its causes and remedies, anisometropia, and a discussion of shortsighted and farsighted persons. Book II treats for the most part of the provision of lenses for the relief of defective vision, and opens with a discourse on the invention of spectacles, followed by descriptions of various kinds of glasses, of concave, convex and plane lenses, and of protective glasses. Later the numeration of lenses is discussed, a portion of the book of the greatest interest to the ophthalmologist. The size of the prescribed lenses is considered, and the means by which the strength of both concave and convex glasses may be recognized through testing the focal distance of each lens by "a person with perfect sight."

An account of the principal methods of determining the refraction follows, calling attention to the decided difference between congenital and acquired visual defects. "Ordering glasses for the relief of presbyopia in the Spain of 1622 was quite as satisfactory and efficient a process as that adopted nowadays by jewelers' shops and department stores. If the patient was at hand, the following rules obtained; for a man between thirty and forty years of age, a convex glass of two degrees is required; between forty and fifty, two and a half degrees; between fifty and sixty, three degrees; sixty and seventy, three and a half degrees; seventy and eighty, four degrees; after that period, five or even six degrees." The degree closely approximated our diopter. For some unknown reason, Valdez believed that women required somewhat stronger presbyopic lenses than men. He found the former more delicate and with weaker vision.

The dialogues treat not only of the subject of optics, but include discussions of many medical subjects, and of the relation of religion to physiology. The first conference is about short, weak, or injured eyesight; the second, unusual forms of defective, confused, and unequal vision; the third, cases of incomplete correction of visual defects by glasses, and difficulties experienced by patients in wearing glasses; and the fourth is about what we would call opera glasses—small telescopes then used for seeing at a distance.

"The actual procedure in choosing reading glasses described by Valdez," writes Dr. Wood, "does not essentially differ from certain methods much employed in the present day, except that the Master several times insists that glasses are not curealls—thus coming directly in conflict with some of our modern ophthalmologists—and that the state of the visual apparatus itself (its diseases for instance) and the condition of the general health should always be borne in mind, a contention that raises him miles above the refractionists of the department store or even of the optometrical variety." Valdez was opposed to the use of the monocle as making the eyes unequal. He knew well the use of stenopaic lenses. He counsels that in ordering glasses for myopes, these must not diminish the apparent size of the object, nor must the purchaser choose glasses so strong that they pain or tire the eyes—it is far better to wear lenses that do not afford the most perfect vision in the distance, since they are more comfortable and are not a strain upon the eyesight. In Valdez's time, protective glasses were made in all the colors prevailing today—light yellow, dark yellow, red, green and blue.

Seventeenth Century Therapeutics.—An article in a recent issue of the New York *Tribune* describes in part the contents of a medical book published in 1669 which was once the property of William Penn. The volume has recently been given to the Philadelphia College of Pharmacy and Science. The title of the book is *Chemical Dispensatory,* and some of its prescriptions are unique in the history of medicine. It states that "plants that represent the part of man afflicted are wholesome." For instance, walnuts, chestnuts, etc., having heads, are good for disorders of the head; likewise, the eating of liver cures liver trouble, kidney beans are good for kidney troubles, and plants with swellings relieve tumors. A cure for socalled melancholy was a live pigeon cut into and laid on the head while the blood was still warm. Another cure was made of rubies, either drunk or hung around the neck. This would protect also against the plague, evil dreams, frightful thoughts, and keep the baby safe.

The bloodthirstiness of some of the remedies is startling. The most drastic prescription calls for "the blood of a young man taken in May." If this were not available, goat's blood could be substituted, "the goat being a cheerful creature, swift, proud, quick of hearing, and ravenous." Similar qualifications were not apparently demanded of the young man. Another prescription requires "the carcus of a redhaired man, whose blood is thinned and flesh therefore better, whole and sound, twenty-four years old, not dying of disease, but killed." What ailment this cures is not stated. Dr. Julius W. Sturmer, dean of science in the Philadelphia College of Pharmacy and Science, is quoted as saying that this bloody remedy probably originated many years before the book was written. Redhaired persons were rare in southern Europe, particularly among the Romans. Lighthaired men, therefore, were always conspicuous, and usually from the Northern tribes, hence barbarians or slaves or captives, and not in the eyes of that period to be regarded as human beings.

Editorial Articles

GOITRE HEARTS

The subject of goitre and its treatment is of perennial interest to the medical man and of considerable concern to the public at large. There is a great deal of goitre in this country and the question of treatment, of course, varies somewhat. The shrewd physician and the keen surgeon do not, as a rule, see eye to eye with regard to treatment. The physician naturally believes in medical rather than surgical methods to effect improvement or cure, while the surgeon is likely to resort to operative measures at once with the same object in view. There are cases, however, in which there is no divergence of views as to treatment. Some are obviously medical, while others are just as patently surgical cases.

That there is a relationship between thyroid disease and the heart is an old belief, and one to which German writers, in particular, have drawn attention. It is an important point, for the reason that in certain cases such a connection should preclude operation and it is well to know what type of goitre hearts renders surgical methods risky or dangerous.

To this number of the JOURNAL Dr. S. Strickland Goodall contributes an article dealing with the matter at issue. He is one of the first authorities on the heart in Great Britain and has had much experience in this direction, and therefore his words may be considered to carry great weight. After pointing out that, roughly speaking, goitre hearts fall typically into two main groups, 1, pneumomechanical; and 2, thyrotoxic, he concludes that in the case of the pneumomechanical heart the operative risk is comparatively slight, mainly because it is not poisoned or degenerated, while in the case of the thyrotoxic heart, the risk is relatively high, because the heart is not only exhausted but poisoned and degenerated as well. Moreover, in both types, according to Goodall, recovery after operation is frequently incomplete, and in the thyrotoxic cases, as would be imagined, being slower by far than the pneumomechanical.

It is also pointed out that the most complex and difficult of all cardiac cases to assess, so far as goitre is concerned, are those in which the subject in early life manifested some such condition as rheumatic fever which definitely damaged the heart. It goes almost without saying that in cases of this nature it is practically impossible to determine how much of the damage is rheumatic and how much thyroid in origin.

Dr. Goodall's article is illuminative and suggestive and should be read closely and studied carefully. As said before he has had a wide experience. Dr. James Berry, who has operated for exophthalmic goitre more frequently than any other British surgeon, sends the majority of his cases to Dr. Goodall for cardioanalysis before operation.

It may be pertinent to inquire how often the thyroid is injured by toxemia of an intestinal origin. Some authorities have no hesitation in stating as their opinion that this is what happens in the majority of cases. It is also recognized or, perhaps, it may be wiser to say that such is the belief of many leading members of the profession, that rheumatism is largely caused by intestinal toxemia. Therefore it would seem that the heart is affected by both thyroid disease and rheumatism and in both instances, too, it is probable that the toxemia which causes the damage is of intestinal origin. Granted that this view is even partially correct, does it not supply another convincing proof of the validity of Sir James Mackenzie's contention that disease should be attacked in its beginnings and not allowed to develop? If, for example, intestinal toxemia were so dealt with that it is not allowed to develop, to put it mildly, there would not be nearly so much thyroid disease nor rheumatism and consequently fewer goitre heart and less cardiac damage from rheumatism, which is said to be the chief cause. By such simple means the prevalence of heart disease would be vastly diminished. Perhaps there are too many ifs in this editorial. At the same time the matter appears to be worth discussion.

THE ENDOCRINE GLANDS AND ARTHRITIS

The primary cause of arthritis is not known in spite of the contention of some that infection of the gums and teeth and oral sepsis generally are usually the origin. Belief in pyorrhea and infected tonsils and so on as the main causes of arthritis is not so active or prevalent as formerly. Indeed, it seems to be recognized now that oral sepsis as the source of many complaints, serious and slight, has been exaggerated. It was almost an obsession with some. But the pendulum is beginning to swing in another direction and the rôle of the mouth in the causation of disease is commencing to be estimated differently. The effect of endocrine derangement is at present being suggested as more likely to be responsible for arthritis and for dental caries as well. Broderick, who contributed a powerful original article to our last special number on endocrinology, said his re-

searches led him to believe that dental caries may be due to calcium hunger owing to disturbance of the normal balance of the endocrine glands. Probably of the parathyroid glands in particular, as it seems to be held by those who have investigated the subject that it is the parathyroid glands which control the calcium content of the body.

Llewellyn in the *Medical Press and Circular,* April 4th last, writing on the cause of arthritis declares that he feels certain, too, that in the imbalance of the endocrine glands resides the clue to the intermediate pathology of, at any rate, some forms of arthritis. Llewellyn pursues these interesting speculations further and points out that states of hyperthyroidism are frequently met with in association with arthritis and the victims of hyperthyroidism exhibit a lowered sugar tolerance and lowered sugar tolerance seems to be a metabolic disability common to both gouty and nongouty forms of arthritis. Summing up his arguments in favor of the hypothesis Llewellyn notices that psychic factors acting via the endocrine glands and exposure through depression of the oxidative functions of the blood may determine each in their several ways, a lowered sugar tolerance. He concludes that local infective foci, whether dental or other, are not the sole agents capable of initiating the chain of pathological events that eventuate in arthritis and with Pemberton, who has made close studies of the question recently, Llewellyn is strongly of the opinion that "it is safer and certainly more reasonable to believe that a variety of factors, many types of infection, exposure to cold and wet, chronic intestinal conditions, of which we have only imperfect knowledge, and possibly even less ponderable interglandular disturbances, may induce the substratum, partly illustrated by a lower sugar tolerance, which is shown to accompany this disease so closely."

Evidence is forthcoming daily of the immense influence over health exerted by the hormones and it appears that it is being emphasized more and more daily that glandular therapy will be the treatment of the future. The time for this is not yet. There is much to be learned with regard to the endocrine glands before the Utopia of glandular therapy is reached. There is a good deal of sifting wheat from the chaff to be done. But advance is being made and the outlook is hopeful. Another point which cannot fail to impress those who are following the trend of modern medicine is the realization of the effect of the mind over the body and vice versa.

Psychic factors have a profound influence upon the well being of the body. Mental shock or even more profoundly continuous anxiety or worry may bring on numerous diseases. Llewellyn says that these factors may determine the onset or exacerbation of arthritis, because through the medium of the endocrine glands, they induce a lowered sugar tolerance. In many directions our views as to the causes of disease and consequently of treatment are being revised and will be further revised and discoveries with respect to the functions of the endocrine glands and of advances in psychology have had much to do with our revised opinions. It may be affirmed that we are on the threshold of changes in the practice of medicine quite as revolutionary as those ushered in by the discovery of bacteriology.

THE RESPIRATION IN BASEDOW'S DISEASE.

The respiratory disturbances encountered in exophthalmic goitre are the consequence of the Basedow syndrome. They depend upon it entirely and are not the result of a rhinopharyngeal lesion or a concomitant pulmonary process. All subjects of this morbid process present a rather marked polypnea which increases upon exertion, usually in a mild degree. Thus reading aloud will slightly increase the number of respirations. On the other hand, more strenuous exercise is less well supported by the patient, causing an increase of the tachypnea. The latter is generally in direct ratio to the tachycardia, but the parallelism is not absolute and it may be said, in a general way, that the respiration is more stable than the pulse.

In general, the respiratory rhythm is regular; but occasionally it is irregular and jerky, during either inspiration or expiration, indicating a true respiratory trembling, a topographical modality of Basedow trembling, and, like it, susceptible of increase from fatigue or emotion. Thoracic amplification is below normal so that the respiratory index is low, even when one takes into consideration that women represent the largest number of cases. The same is true of diaphragmatic incursion which is diminished.

The voluntary apnea test shows that in Basedow's disease there is a considerable diminution of the possibility to suspend breathing, the average length of time being eighteen seconds, instead of fifty, which is normal. This reduced time indicates oxygen hunger in these subjects and contrasts with the length of voluntary apnea in myxedema.

Spirometric examination reveals a distinct decrease of respiratory capacity, while the study of respiratory debit with Pech's monometric apparatus shows that the maximum respiratory debit is greatly diminished, especially during expiration. This phenomenon accords with the results obtained from the study of the basal metabolism in exophthalmic goitre. Prodigal with their reserves, Basedow sub-

jects with considerably increased respiratory functions are in a state of permanent polypnea in order to repair the loss resulting from exaggerated consumption of oxygen, either in the tissues or in lungs. This fact is quite in accord with the disturbances of pulmonary ventilation described not long ago by Professor Achard.

The oculorespiratory reflex is usually positive in the vagotonic sense in the same sense as the oculocardiac reflex. However, there may be a dissociation of these two reflexes, a condition readily understood on account of the various responses given by the different oculovisceral reflexes. Compression of the eyeballs acts on the respiratory debit in general, especially on the expiratory debit.

BUNK, ESPECIALLY MEDICAL.

Slang is a great thing, a very human form of speech, apt, humorous and as a rule logical. Purists whose hearts have about as much of the milk of human understanding as a dried apple decry its use. To them, words in the making are an anathema. They approve only old, threadbare words, words which lack the zest and vigor of youth, which express an idea with ponderous dignity instead of crisp freshness. Yet many of these etymological outcasts can boast a distinguished lineage; boob is the old Spanish *Bobo,* a simpleton, and from the latter word we get the expressive simp. There is a short, pungent word which we Americans think is all our own, bunk, derived appropriately from the patronymic of an early member of the House of Representatives, one Colonel Buncombe. Really though, it came into the language with the Danish invasion, *bunke* in the Scandinavian tongues signifying anything which swells out, also, a heap. Thus it is seen that as used today bunk is not far away from its original meaning.

The word means pretension of what one is not, the assumption of what is not true, for the purposes of deceit. It carries with it the idea of swank, a perfectly good Scotch word which crept down from the north, something puffed out or padded out, a bombastic person. It is a particularly human quality, something to which most of us are given in little ways and a few have it as their outstanding characteristic. Its manifestations are protean, none of us likes to admit how really insignificant we are, even to ourselves, and so in some way or another we preen ourselves as peacocks, though we are but sparrows. Our magazines are full of it. Big business teems with it. It is the daily bread of many professional men. Properly controlled it partakes of the quality of proper pride. In a more advanced stage it is ludicrous. It may reach the plane of the near criminal and it may even become so malignant that is destroys its victim. Its struttings and its posings are pitiful, its deceits may be malicious and it is altogether reprehensible, but it will amass great fortunes and continue to advance men to power until that millennium when all men will despise self-deception and therefore cease deceiving others. Those sparse hedges with which recent medical graduates used vainly to try to hide their youth were the first symptoms of the acquirement of the bunk habit. The owlish consultations in which the older physician pompously pronounced that "the treatment is progressing satisfactorily but," were another pathognomonic sign. The concealing of the simple drugs in halfcaste Latin, the designation of nosebleed as epistaxis, cold sores as herpes and a stye as hordeolum were part and parcel of this bunk.

It is upon this simple practice of the palpation and adjustment of the vertebræ of the spinal column with the hands for the purpose of releasing the prisoned impulse, that chiropractic "has made the most astonishing growth of any profession in the history of the world" to quote from a recent advertisement. That's quackery in somebody outside the profession of medicine, but when rest and a tonic are prescribed for the overwrought nerves of an overfed, underexercised representative of the idle rich by a member in good standing, why that's—well—just a little harmless bunk. Think of the drool to which the conscientious attender of medical societies has listened. Consider the bunk laden schemes by which the obstetrician, who was once gratified beyond measure by a twenty-five dollar fee, arrived at that proud pinnacle where no honorarium of less than five hundred dollars can be considered. Compute the millions of gallons of useless nostrums which have been poured down the willing gullets of the gullible public. Yes, in the language of a recent novel, "we need debunking."

But there is a saving clause to all of this. Many and many a physician is following his calling in mental uprightness and that pride which will not stoop to petty deceit, which will not cavil with the truth nor shirk the responsibility for not knowing what is the matter with the patient and how to relieve his present difficulty. The research branch of medicine is singularly free from bunk, yet there are times when the publication of long protocols about guineapig A-47 in nonresearch journals smacks strongly of the vice. The profession has time and again been led astray by some bunk method of treating sick bodies and warped souls but—and here lies the virtue—always after disillusionment it has sought the straight and narrow way of careful thinking there to expiate in the ashes and sackcloth of selfhumiliation the sin of following after

false gods. And after each incursion into these specious paths we have been purified and strengthened and those to whom we are servants have benefitted thereby.

A STUDY OF THE COFFEE QUESTION.

"The history of human experience, as well as the results of scientific experimentation, point to the fact that coffee is a beverage which, properly prepared and rightly used, gives comfort and inspiration, augments physical and mental activity, and may be regarded as the servant rather than as the destroyer of civilization." The foregoing is a quotation from a detailed report made by Prof. Samuel C. Prescott, head of the Department of Biology and Public Health of the Massachusetts Institute of Technology. A three years' study of the coffee problem has just been completed by the Institute, with Professor Prescott as director, the aim being to clear up many disputed questions and traditions regarding the composition of coffee, its physiological action, and the best way of preparing the beverage from the roasted bean. A summary of some of the outstanding statements of the report follows.

The statement is made that, after weighing the evidence, a dispassionate evaluation of the data surveyed led to no conclusions that coffee is injurious to the large majority of persons. It was found that, quite to the contrary, it has a remarkably stimulating and fatigue relieving effect, due to the action of the caffeine upon the central nervous system. Heart action is mildly stimulated, muscular capacity increased, and the ability to concentrate and mental activity stimulated. Coffee does not draw upon the physical reserves; nor does it have a depressive aftereffect. "The activity of the organism is speeded up for a time, then returns to the normal level. . . . The average cup of strong coffee contains about one and a half or one and three fourths grains of caffeine. This is ample, in some individuals, to give a quicker heartbeat, hence to increase the circulation, and activate more pronounced mental processes. Other individuals may require two to four times as much to provide the same degree of stimulation. If individuals are especially sensitive to tea or coffee, its use, except in extremely limited amount, is not to be recommended. In this respect, it should be treated in exactly the same manner as are many kinds of food, meat, shellfish, eggs, milk, or fruit which do not agree with one person or another. These food idiosyncrasies are now known to be not uncommon." The ability to take coffee clear, but not with cream, is due to inability to take care of the fat element. It was found also that there was some difference in result when pure caffeine was given in aqueous solution, and when given in the form of strong coffee containing equivalent amounts of caffeine. In general, the tolerance for the caffeine in the coffee was higher than that for the pure caffeine in the water. Speculation on the reasons for this, together with observations on the chemistry of caffeine, suggested that caffeine may exist in beverage coffee in a different form from that in the solution. Experiments were made on rabbits as to the desirable, tolerable, objectionable, and lethal results of caffeine, and it was found that the amount lethal to a rabbit depends upon the animal's body weight. Assuming the same caffeine tolerance per kilo in the case of man, it would require one hundred and fifty to two hundred cups of ordinarily strong coffee, taken at one sitting, to kill a man weighing 154 pounds. It is stated, however, that these figures cannot be taken as absolute. A surprising fact came to light, in that, after a study of a vast amount of the literature of several countries, no important information could be found on the best methods of preparing coffee.

PERFECT STANDARDS

Man has been seeking the ideal test of human perfection for a long, long time. The ancient Egyptians hit upon one by some mysterious process. They took the length of the middle finger as the unit, and standardized the head into so many finger lengths, the trunk into so many, the legs and the feet into so many, the breadth of shoulders in the same way. The Greek artists elaborated similar tests of physical perfection. Dürer and other great artists of the middle and later ages spent much time and effort in the same direction.

More strictly along health lines, the earlier enthusiasts in physical education in this country tried, by the study of measurements and tests of a large body of youth, to establish a standard to which they hoped, and more or less believed, all the rest of humanity could be approximated. Later, by adding, subtracting, multiplying or dividing various measurements, they tried to establish a vital index—a coefficient which would show, at a glance, just where a man stood with regard to physical function. These vital indices all proved to be will-o'-the-wisps.

The recent search for nutrition standards is, to a considerable extent, a repetition of this running after a hard and fast ideal, and the results are likely to be much the same. Not less than a dozen standards have been worked out in Europe and in this country. None of them agree; all approximate an average, but that is about as far as they get. After all, while weighing and measuring are a lesson and a stimulus to the person weighed and measured, we are not

justified in making of them more than they deserve. Variations from the average may not, on the whole, be good, but they occur normally and to a wide degree; moreover, variation has been at the bottom of evolution.

After all, are we not making too much of weighing and measuring, and not enough of malnutrition? The best and most farreaching practice would seem to be to see that a child is free from disease or hampering defect; that he receive a diet which contains all that he ought to have, in quantity as well as quality; that his feeding and other habits are what they should be; that he have ample rest and exercise and a normal mental atmosphere. Every child is deserving of these and under such conditions will reach his acme of growth and development, even if he falls more than ten per cent. below the average weight for his height, has a low *pelidisi,* an unsatisfactory Bernhardt index, or what not.

THE GARDEN CITIES OF RHEIMS

An interesting and successful experiment in building garden cities is being carried out in the vicinity of Rheims, according to *The World's Health.* The movement is not the result of the destruction wrought in the city by the war, for the plan was conceived originally before the war by a group of philanthropists with a view to raising the falling birth rate. For this purpose a capital of 1,250,000 francs had been collected and an anonymous society incorporated to provide housing at reasonable rates for "large families," including all those with a minimum of four children under sixteen. When the war broke out a number of houses had been built, but most of these were destroyed later by the bombardment. This blow did not discourage the enterprise, for, as soon as possible after peace had been declared, a plan for the construction of two garden cities, one of six hundred and the other of four hundred houses, was drawn up. These were to be located on the outskirts of Rheims. It was not until almost the beginning of 1921, however, that all the obstacles and difficulties to actual construction could be overcome. When the work was actually begun it went on rapidly. During the early part of the year five hundred tons of building materials were transported daily, and later fifteen hundred tons. The first garden city was completed in less than a year.

This city is now inhabited by 3,500 people, 2,200 of whom are children. It covers an area of about seventy-five square acres, each house occupying about sixty square yards, each garden about 360 square yards, and the remaining space being devoted to city squares and playgrounds. There are fifteen different types of houses, with lawns and gardens, and some have studios for the handicrafts, with the necessary equipment. There are also various shops and a community bakery.

Public health and child welfare activities are in full swing. A big building called the Children's House contains prenatal and baby welfare clinics, a milk station, a crèche and day nursery, and rooms for classes for the older children in housekeeping, cooking, sewing, laundry and other house crafts. Another big building has been named Everyman's House, and this, when completed, will be a kind of community club house, with a library, dispensary, recreation hall, rooms for meetings, gymnasium, baths, etc. A Roman Catholic Church is being built, and will be followed by one for Protestants, if enough come to live in the city. School buildings and an open air school have been planned. The garden city is located on high ground, and the windows of the homes command a lovely view of the surrounding hills and fields.

The rents for the homes are charged on a basis of the number of children in the family—the more children, the less rent—and the income from these suffices for the upkeep of the buildings and the street. The social welfare work is supported by private donations. Each month shows an average of three deaths to ten births.

SEX INSTRUCTION FOR CHILDREN

What Will You Tell Your Child, and How? is the title of a little pamphlet published by the Chicago Department of Health as No. 43 of its Weekly Bulletin. The writer is Dr. Herman N. Bundesen, Commissioner of Health of Chicago. The pamphlet has been prepared for the purpose of furnishing to parents, as the best teachers of sex matters to their children, information that will enable them to give instruction that will satisfy and guide the child's inquiring mind without unduly stimulating his curiosity about sex, and "so direct the child's sexual life and habits that he will be clean, wholesome, and will develop physically and mentally as nature intended he should." Although the writer states that his plan of instruction may be used, with a few changes and special adaptations, for girls as well as for boys, the boy's sex life is the one discussed. He announces that a more detailed discussion of methods of instruction for girls will follow.

The pamphlet is a practical little guide. The subject is taken up following the three periods of boyhood. The first period, from infancy up to eight years of age, requires facts best given by the mother on the care of the sex organs, and plain, truthful answers to questions from the child about the origin and renewal of life, adapted to his understanding. This period is sometimes called the age of mythology. The second period, from nine to fourteen, the age of chivalry, demands efforts from both parents toward the wholesome development of the boy's emotions

and imagination, with stress on the need of clean thoughts and healthy physical living. "He needs also the facts concerning the development of the generative organs, the normality and naturalness of seminal discharges, and advice on the control of the impulse of self-abuse." The third period, from fifteen on, is called the age of civic awakening. Now comes the father's turn to instill the principles of self control and chastity, the danger of sexual diseases, and the love of family life. "The preliminary instruction necessary for marriage, the meaning of marriage, fatherhood and motherhood, facts affecting the welfare of the individual, the nation, and the race, should be dealt with. The child should be warned that sexual intercourse before marriage may mean: 1, a bad habit; 2, venereal disease; 3, pregnancy of an innocent girl; 4, spoiling a girl's life; 5, breaking up homes and other matters. Much more detailed advice to parents follows this preliminary outline. At the end of the discussion is a rather full list of references for further reading.

News Items.

Infantile Paralysis Research.—The Harvard University Infantile Paralysis Commission has undertaken work to determine the cause of infantile paralysis and, if possible, a remedy. The research will be conducted at the Harvard Medical School.

Alumni Dinner of College of Physicians and Surgeons.—The class of 1898 of the College of Physicians and Surgeons of Columbia University held its twenty-fifth annual dinner at the Hotel Commodore. Seventy-nine members attended. Dr. T. S. Arbuthnot, of Pittsburgh, was toastmaster.

Senate Inquiry of Diploma Mill.—Investigation of socalled diploma mills was ordered by the Senate through adoption of a resolution introduced by Senator Copeland, M.D., of New York. The committee on education and labor, of which Senator Walsh, Idaho, is chairman, will have charge of the inquiry.

Instruction in Use of Insulin.—The University of Pennsylvania has started a third course of instruction in the use of insulin. Work started on December 17th and lectures and clinics will be given on Mondays, Tuesdays, Thursdays and Fridays from two to four and from four to five for laboratory work.

Montgomery Ward Memorial.—Northwestern University Medical School has received an endowment of $3,000,000 for a medical and dental school on the McKinlock Campus on Chicago Avenue. The donor, Mrs. Montgomery Ward, gives the money as a memorial to her husband and it will be known as the Montgomery Ward Memorial.

Obituary.—William Whitford, official medical stenographer for the state, district, county and international medical societies, died suddenly in Chicago on December 11th of myocarditis. Mr. Whitford was sixty-six years of age and was an honorary member of the Tennessee State Medical Society. A resolution commemorating him was passed by the board of trustees of the American Medical Association.

Rockefeller Foundation Elections.—At its regular December meeting, the Rockefeller Foundation elected to membership in its China Medical Board, Professor Paul Monroe, Teachers College, Columbia University, and to membership in its International Health Board, Dr. John G. FitzGerald, professor of hygiene and preventive medicine, and director of the Connaught Antitoxin Laboratories, at the University of Toronto.

Personals.—Dr. Walter Timme delivered a lecture on the automatic glandular mechanism, on Monday, December 17th, at the New School for Social Research, 469 West Twenty-third Street, New York.

Professor Robert A. Millikan, Ph.D., of the California Institute of Technology, Pasadena, recently was awarded the Nobel prize for physics. He has also been awarded the Hughes medal by the Royal Society of London, England.

Child Health Meeting.—A meeting for physicians and public health workers interested in child health particularly will be held at the New York Academy of Medicine on Thursday, January 3, 1924, at 8:30 p. m., under the auspices of the Public Health Committee of the Academy. The program follows: The principal problems of child health work in New York City, by E. H. Lewinski-Corwins, Ph.D., executive secretary of the committee; Standards of nutrition clinic, by Dr. Charles Hendee Smith; The safeguarding of the mental health of the child, by Dr. Arnold Gesell, M.D., professor of child hygiene, Yale University, and Community responsibility for child health, by George B. Vincent, Ph.D., president, Rockefeller Foundation.

Disabled Exservice Women to Be Admitted to Soldiers' Homes.—The Secretary of War has authorized announcement of the action of the board of managers of the National Home for Disabled Volunteer Soldiers, in making provision for admission to these homes of exservice women who have incurred disability. At a meeting of the board of managers held at Dayton, Ohio, September 14, 1923, a resolution was adopted to set aside a separate building at the Danville, Illinois, branch for the care of exservice women and for separate facilities to be made at the Northwestern Branch, Milwaukee, Wisconsin, for tuberculous patients. All women honorably discharged from any governmental war service are eligible for admission.

Ohio Botanical Society.—The Ohio Botanical Society organized for the establishment of a botanical garden in Cincinnati held its first general meeting on Friday evening, December 14. James Albert Green presided. Mr. Green presented an illustrated lecture on the great botanical gardens of the world, in place of Dr. Caswell A. Mayo, of the Wm. S. Merrell Company, who had prepared the lecture but who was suffering from ptomaine poisoning and therefore unable to be present. Mr. Green showed two hundred lantern slides, which included illustrations of the great botanical gardens of the world, and told of the educational work being carried on by the Brooklyn Botanical Garden as an excellent model of the kind of service such an institution could render to a city.

Foreign Correspondence.

LONDON LETTER

(From our own correspondent)

London, *November 9, 1923.*

NOBEL PRIZE FOR MEDICINE FOR 1922.

The Nobel Prize for Medicine for 1923 has been awarded to the Canadians Dr. F. G. Banting and Professor J. J. Macleod, of Toronto, for the discovery of insulin. The Nobel Prize for Medicine for 1922 has been divided between Professor Archibald V. Hill, professor of physiology at University College, London, and Professor Otto Meyerhof, professor of physiology at Kiel University. Professor Hill was unaware that his work had been considered, and had had no intimation of the award, when his wife who was glancing at the newspaper informed him of the honor bestowed upon him. Upon arriving at the college, Professor Hill found a telegram for him from the President of the Caroline Institute, Stockholm, informing him of the award. The fact that he shares it with Professor Meyerhof, has given peculiar personal pleasure to him, as they are close friends and both have been occupied with research work on muscular contraction. He took up the work in 1910, and with the exception of the years of war, has been engaged upon it ever since. Educated at Blundell's School, Tiverton, and Trinity College, Cambridge, Professor Hill was Third Wrangler in 1907.

It was Sir Walter Fletcher, now secretary of the Medical Research Council, his tutor at the university, who induced him to take up physiology, and Professor J. N. Langley, professor of physiology at Cambridge, who suggested the line of investigation. Sir Walter Fletcher and Professor F. G. Hopkins in 1908 had investigated the formation of lactic acid in muscles during exercise and its removal during recovery from the effects of exercise. Professor Hill continued the work and approaching it as a mathematician and physicist carried it on by a totally different physical technic. After the war Professor Meyerhof took up the subject on the original lines of Sir Walter Fletcher and Professor Hopkins. The phenomenon with which Professor Hill has been particularly concerned is the recovery process, which occurs after exercise has been taken. Other matters which have engaged his attention include the nature of nervous excitation, the principles by which the nerve transmits its impulse, the carriage of oxygen and carbon dioxide by the blood, and the elastic properties of human arteries. Professor Hill, who is an extremely modest man, attributes the award to him of the Nobel Prize to the fact that he is fundamentally a physicist, and has been singularly fortunate in finding problems a physicist can work at, in physiological subjects.

LARGE GIFT FOR RESEARCH WORK IN DEAFNESS.

The Senate of the University of London has announced recently that important extensions of their research work for the benefit of the deaf is about to take place. This has been rendered possible by their acceptance of a gift of £10,000 to found a chair of otology, and the donor, Mr. Geoffrey E. Duveen, intends to allocate a further £15,000 to the University College Hospital for the provision of the most complete and modern treatment of the deaf. The double gift is made in memory of the donor's father, Mr. Henry J. Duveen, one of the founders of the art firm of Duveen Brothers, of London, Paris and New York. Mr. Geoffrey Duveen, who has himself suffered from ear trouble for years, lost his only brother from the same cause, following an attack of scarlet fever.

SAFETY OF THE WOMAN WORKER.

At a meeting of the British Industrial Safety First Association, held in London a few days ago, Miss H. Martindale, superintendent inspector of factories, read a paper on Safety First and the Woman Worker, in the course of which she said that according to the last report of the chief inspector of factories, 11,095 reportable accidents occurred to women and girls during the year 1922. These numbers, although large, were small compared to the number occurring to men and boys, which was eight times as much, in spite of the fact that the number of men and boys engaged in industry was only twice that of women. The temperature of the workrooms seemed to have a considerable influence on accident risk. The factory act required that a reasonable temperature should be secured and maintained in workrooms, and it had been the aim of inspectors to insure a temperature of about 60° to 65° F. in workrooms in which a sedentary occupation was carried on. Scientific research had shown that accidents were at a minimum at temperatures between 65° and 69° F., increasing rapidly at higher temperatures and slowly at lower temperatures. A warm but well ventilated room would result in a lessened accident record. Defective lighting was another cause of accidents.

EXPLANATION OF THE CAUSE OF GROWTH.

Dr. Frederick Gowland Hopkins, professor of biochemistry in the University of Cambridge, after having been presented with the gold medal of the Royal Society of Medicine at the house of the Society in London, gave a short address. He pointed out that growth was the predominant attribute of life, and though little was known of its inner meaning there was a number of points connected with it of practical importance. He was of the opinion that, as in the case of a contraction of a muscle, it occurred only in response to a stimulus. There was, for instance, the case of the pituitary gland, which, if overactive, resulted in gigantism. Lower organisms again, such as yeast, only grew vigorously and normally as the result of a special stimulus, and the same occurred with bacteria. The behavior of protozoa was peculiar. A single individual would not multiply unless the medium in which it was grown was of very small bulk; if, however, a pair of protozoa were placed in the medium they did not multiply twice faster, but twenty times faster. Multiplication was solely by division, and the explanation of the rapid increase in the speed of division was due to the fact that each individual, while dividing, secreted into the medium a material that stimulated

growth. Consequently, if two individuals were present they stimulated each other. As for the animal body, Professor Hopkins pointed out that though the adult animal, as a whole, had ceased to grow, the cells of its tissues, transferred to a suitable medium, did not cease to grow and here he said we were touching on the great problem of cancer. The effect of vitamines on growth was a stimulus, for experiments showed that the addition of the minutest quality to the food of vitamine deprived rats produced a remarkable and immediate growth. Finally, he pointed out that while the pituitary was a tissue highly specialized for the general control of growth, any living cell of itself could supply stimulants for growth. When cells were living in community, one cell could stimulate the other to some extent.

EVIDENCE IN FAVOR OF MODERATE DRINKING.

Professor Starling, the well known physiologist, has written recently, or rather has edited, a book in defence of the moderate consumption of alcohol. Most of the book is written by Professor Starling, but in addition there are chapters by Sir Frederick Mott dealing with the relationship of alcohol to mental disorders, by Dr. Robert Hutchison on alcohol as a medicine, and by Professor Pearl on alcohol and mortality. Dr. Starling concludes that the moderate use of alcohol is beneficial and proceeds to the further conclusion that national abstinence by common consent would be a great mistake. Sir Archdall Reid read a paper recently at the meeting of the *Ligue Internationale des Adversaires des Prohibitions,* in which he stated that in his opinion, from the scientific point of view, national total abstinence from alcoholic beverages would be disastrous.

A MEDICAL YEAR BOOK.

In a short time *The Medical Year Book,* written by Charles R. Hewitt, late librarian of the Royal Society of Medicine, London, will be published by William Heinemann, Ltd., London. The object of the year book is to provide a handy volume conveniently arranged and classified and intended to serve as a guide to the current activities of the medical profession of Great Britain.

LATIN AMERICA LETTER

(*From our own correspondent.*)

BALBOA HEIGHTS, *December 11, 1923.*

HOW THE CANAL ZONE PHYSICIANS FIND AMUSEMENT.

Perhaps our medical brethren in the United States sometimes wonder how we dwellers in the tropics employ ourselves when we are not at work. There is a popular belief that the heat, humidity and isolation tend to induce a mental and physical attitude which causes rapid deterioration of mind and body, that the *mañana* habit is speedily induced and that for the most part we care for little except the daily siesta and the monthly payday spree. Nothing could be farther from the truth. We have learned from observation that liquor in the tropics is a grave danger, that physical slothfulness is a serious menace, and that a combination of the two is absolutely deadly. Therefore, despite the fact that the average medical employee works every day at least from 8 a. m. to 4 p. m., few of us do noontime hammock fatigue and practically every one of us engages in some form of outdoor sport whenever the weather permits. In a climate of perpetual summer this means practically every day in the year when the rain does not descend torrentially, and as a result most of the physicians wear a splendid coat of tan. There are golf courses at Panama City, Fort Amador, Fort Clayton, Pedro Miguel, Gatun and Fort Davis and every afternoon a procession of perspiring physicians may be seen pursuing that ancient and honorable game which is altogether a vanity and a vexation of the spirit. For the younger men there are a number of good tennis courts and every afternoon buses take swimming parties to the various beaches, where all ages and both sexes disport themselves aquatically. There are also several good swimming pools with excellent instructors, and the Isthmian child who cannot swim is a *rara avis in terræ,* as Horace was wont to say. The fishing is unexcelled and there is hunting a plenty. When one has spent an hour killing a *pappagalla* with a rod and line or has hunted deer all day in the jungle he is apt to feel that he has had some exercise. Several physicians are regular patrons of the gun clubs, and a few ride horseback.

Unfortunately we are rather short on theatrical entertainments, but we have a season of really good opera each year and for those who take the trouble to learn Spanish there are the *variedades* (Iberian vaudeville) and any number of dancers of the Castillian school. The movies we have always with us; always troupes of musicians are passing through to Central and South America and there is a wide variety of social entertainment, official dinners, army and navy hops and receptions. Of the latter, there is almost a superfluity because all the great and the near great pass this way sooner or later and must be properly greeted by the punchbowl-handshaking route. Then there are the *tertuliias* (informal dances) and the *gran bailles* (formal balls) which reach their acme in the wonderfully colorful spectacles of carnival just before lent. Carnival begins on the Saturday noon before Ash Wednesday and ends at midnight Tuesday. There are processions each day; everywhere the natives are dancing the *tamborita,* a dance which was locally extant when Balboa made his famous transcontinental transit, the women in the *pollero,* a national dress seen only at that season, and the men in fancy costume; the streets are filled with confetti throwing, serpentine tossing, perfume squirting children; every night there is a costume ball which lasts until time for breakfast; if anyone doubts that this isn't exercise of the most soul searching sort let him participate whole heartedly in one carnival and try to do his work each day!!

A few physicians take their exercise at the bridge table and others across the line in an earthly paradise which knows not Volstead, but there is no intemperance and little lack of healthful exercise in the medical stratum of our society. When the Medical Association meets at Santo Tomas Hospital in Panamanian territory, a keg of beer revives the tired scientists; once in a while there is a nonsynthetic anteprandial cocktail across the line, sometimes a long, cooling rum punch relieves the fatigue of the

day, but of overdrinking among our doctors, there is none.

Once in a while an exploring party visits the San Blas Islands where the women wear nose rings, or makes the journey to the Darien Indians, who wear nothing at all; sometimes a number of physicians go into the interior to open pre-Columbian graves and collect *guacos,* the gold ornaments and clay pottery which have been hidden there for a thousand or more years; there are prize fights, cock fights and bull fights for those who like them; some find an outlet in the various fraternal orders; yes, there is plenty to interest and amuse those who have the initiative and sense of humanity to look about them. As a result, we are a healthy lot, without too much girth, except in isolated instances, with the appetite which comes from the zest of life, and time moves by on speeding wings. Also, we are a highly contented lot. Some of us growl at this or that, as all normals should, but on the whole, we are comfortably at peace with the world, as are our brethren who live in more rugged climes and struggle with recalcitrant furnaces and frozen automobiles. At least we like to think that such is the case.

THE OCTOBER FLOODS.

As told in a previous letter the rainfall for the month of October was above the normal throughout the Canal Zone and immediate vicinity. In the Pacific section the average rainfall for the month was 14.29 inches, in the Central section it was 27.49 inches, and in the Atlantic section it was 34.41 inches. The totals ranged from 12.69 inches at Taboga to 44.35 inches at Agua Clara, while the greatest amount of rainfall recorded on any one day was 12.25 inches at Gatun on October 23rd, breaking all Isthmian records for twenty-four hours in any one month.

With this tremendous and unprecedented downpour the water supply system of the Canal Zone and the terminal cities of Panama and Colon was seriously threatened and damaged at several points. The first trouble experienced was at the 612,000,000 gallon Agua Clara Reservoir, which supplies Gatun, Gatun Locks, Fort Davis and Fort Sherman. The inflow to the reservoir was so rapid that there was grave danger of the water flowing over the crest of the dam in spite of the fact that both spillways were discharging at their maximum capacity. Men were stationed at the dam with a quantity of sandbags to be filled and piled on the crest of the dam and preparations were made to enlarge the spillways as a last resort. For several days it was feared that the water would pass over the dam and destroy it but fortunately it did not reach the top by several inches.

At practically the same time, October 21st, the eight inch water line which runs from Toro Point, where Fort Sherman is located, to Gatun was broken and investigation showed that entire sections of the line had been washed out and that in other places it was under several feet of water. It was impossible to locate and repair the breaks until the flood subsided. This left Fort Sherman without water and it was necessary to take water for drinking from the piers at Cristobal in barges. Temporary repairs were finally made but a considerable sum and much labor must be expended before the line will be safe again.

An extensive landslide between Summit and Gamboa opened the thirty-six inch line which supplies the entire southern end of the Canal and necessitated shutting down the Gamboa Pumping Plant. To meet the emergency thus created water was secured from the Rio Grande Reservoir situated on the west side of the Canal near Camp Gaillard, but as the pipe line from this reservoir is only a twelve inch one where it passes under the Canal at Paraiso, only two thirds of the amount of water consumed daily could be furnished. Two days later this line was destroyed by a landslide and the only other available source of water supply was the Canal itself and a suction dredge was anchored in Miraflores Lake near the Miraflores Filtration Plant, a twenty inch dredge ppie line was run over the hill and pumping immediately begun to the Filtration Plant. To provide against interruption again, two four thousand gallon per minute pumps were installed in the abandoned Miraflores Pumping Plant and as soon as the installation was completed and the Rio Grande line had been repaired, the dredge was released. Permanent repairs are now being made wherever the water lines were injured and with the advent of the dry season this work will be rushed to completion. In the meantime the water supply of the Isthmus is functioning satisfactorily, the purity of the water has been maintained in safe hygienic limits and every emergency has been met promptly and efficiently.

OLD PANAMA TO BE PRESERVED.

Visitors to the Isthmus have been struck with the lack of care which is given to the preservation of the ruined city of Panama. One of the oldest settlements on the American continent, the scene of the embarkation of Pizarro and his victorious return; an Indian village, originally the home of Tobanama, it was there that Balboa claimed the Pacific for his king and it was there that he was executed by the cruel Pedrarius. Aside from the romantic interest inspired by the thought of the loot of Peru which passed through its port enroute to Porto Bello and the Spanish treasury, the place is of medical note because it is believed that there was established the first hospital on the American hemisphere, Santo Tomas Hospital, of which the hospital of the same name in the modern city of Panama is the direct descendant. After the city was destroyed by Morgan, the pirate who afterwards was rewarded for his wanton act by the governorship of Jamaica, the colony removed to the present site of Panama and what had been a flourishing city of 50,000, including slaves, was allowed to fall into decay. Today all that remains is the bridge over which passed the animals and men bearing Pizarro's loot, and the ruined churches and public buildings. Recently the Alcalde of Panama decided to rid this national monument of the squatters who disfigure it and to clear the ruins of the jungle growth which almost obscures them in places. This is being rapidly done and our visitors in the future will be able to view thoroughly and comfortably this interesting place.

DR. JAMES RETURNS TO THE ISTHMUS.

Dr. William M. James, of the Herrick Clinic of Panama City, has returned after a prolonged visit to the United States and taken up again his medical duties at Panama Hospital.

VIENNA LETTER

(From our own correspondent)

VIENNA, *October 31, 1923.*

PROFESSOR TANDLER ON THE MISERY OF THE VIENNA DOCTORS.

The Association of Vienna Socialist Doctors has started a series of lectures on social medical subjects. The series was opened by Professor Tandler, who spoke on the misery of the Vienna doctors. According to Tandler, the doctors are to be divided into two large groups and those dealing with treating patients are to be distinguished from those being in the service of public health. Out of the two groups, only the first one enjoys the advantages accruing from bid and demand. The law of development demands that the number of doctors in the service of public health be increased continually. All these, however, are much behind their colleagues as regards earning, because they are not allowed to carry on private practice. Notwithstanding this fact, the general opinion held is that the medical career is a very remunerative one. This opinion has to be broken; in the first place by awakening the social feeling already in the medical students. The older medical generation entered on a medical career with the ideal intention of helping their suffering brethren. Today, every student wants to educate himself to become a specialist, in order to earn much money. Therefore the whole medical education has to be altered, and reformed. Professor Tandler draws a sharp line between the special therapeutists and those in public service, and states that he will forbid private practice, for a whole group of physicians in public service, in the near future, and will introduce the system of giving one year holiday in every five years, in order to give them the possibility of supplementing their scientific education. He will propose, also, that in the hospitals the patients shall pay to the administrative board of the hospital and not to the doctors. Also the sickness insurance system is to be reorganized in such a manner that these offices shall not be insuring offices in case of sickness, but rather that they shall prevent the occurrence of diseases. The position of doctors can be improved only in such a way, that the doctors subordinate themselves to the public interests.

THE SLY QUACK.

In a village called Bergstein, Germany, a grocer named Stein has settled, who bought and sold colonial goods, and as a sideline, has dealt also with quackery. Soon the sideline became much more remunerative than his principal occupation. His clientele increased to a wonderful extent. Patients from Belgium, Luxemburg and even from France came to consult him. Before his modest house a whole row of fine carriages and motor cars were waiting, bringing leading persons into his consultation room. The inhabitants of the village held in high esteem the learned "doctor," because the patients from distant places greatly improved the economical status of the poor village. The physicians of the vicinity, however, were dissatisfied, because their consultation rooms were emptier from day to day. They, therefore, reported the case to the magistrate, asking him to forbid the dangerous quack from continuing his practice. The magistrate duly summoned him and accused him of treating patients without having the necessary qualifications. "Not at all! sirs," he said, "I am a duly qualified medical man," and produced his diploma. The judge was very much surprised when he saw that the socalled quack had told the truth. He had obtained his diploma from the University of Berlin. "Then how did you come to pose as a quack?" asked the judge. Dr. Stein smiled and answered: "The matter is very simple. I commenced my medical career as a regular doctor, but though diligent, ambitious, and conscientious, I could not proceed in four years so far that I could earn my rent and food. I put forth every effort to succeed, but everything was in vain, so I hit on the idea of basing my existence on the credulity of people." The "quack" went home to his village, and now he continues his well founded practice as a qualified doctor.

CURE OF PARALYSIS.

The Austrian Psychiatric Institute held a well attended meeting recently, under the presidency of Professor Waggner-Jauregg, where the question of the treatment of progressive paralysis was discussed. Dr. Dattner has related the results he obtained in paralytic cases. He said that in in 1912 Professor Hoches stated that during his twenty years of clinical practice he had not seen a single case which would prove the curability of paralysis. This statement was corroborated by Professor Kraft Ebing, who had 2,500 cases under his care, and not one single case could be cured. It is more surprising, said Dr. Dattner, that Professor Waggner-Jauregg has proved to the medical world just the contrary of these statements. This method has sprung from that observation that the feverish conditions act as a favorable influence on the diseases of the nervous system. Thus, it is an experience of a couple of decades that the manifestations of syphilis disappear with the occurrence of an incidental high fever, not to recur for a good length of time. The survival of a high fever raises the resisting power of the organism, and therewith its fight against the spirochetes is alleviated. These experiences are forming the base of the Waggner-Jauregg method. His observations have convinced him that an incidental malaria in a paralytic increases the natural protecting power, being at the disposal of the body, in a much higher degree, than a simple feverish state. On the ground of this fact he produces malaria artificially in his paralytic patients. The high fever setting in annihilates the spirochetes. The higher the fever, the more certain is it that the protecting materials, mobilized to the defeating of the malaria, are annihilating at the same time the spirochetes too. The treatment of the induced malaria is done in the regular way, adding the abundant use of arsenobenzol preparations which support the body in its fight against the spirochetes. Dr. Dattner said that the method of Waggner-Jauregg had been tested in Vienna and Prague in more than three hundred cases. More than half of the patients were totally cured. The Wassermann reaction became negative, the spirochetes disappeared from the blood and the paralytics were able to resume work.

Book Reviews

ENDOCRINOLOGY

Die Krankheiten der Endokrinen Druesen. Von Dr. HERMANN ZONDEK. Mit 173 Abbildungen. Berlin: Verlag von Julius Springer, 1923.

As indicated in the author's preface, this volume is intended for the guidance of the practitioner and the student in a field full of theories and speculations. Accordingly, Zondek has considered it advisable to deal with recognized diseases or clinical complexes and explain the underlying dyscrinisms rather than to study each of the glands of internal secretion in turn. This is in accordance with the view, now generally accepted, that most of the clinical pictures represent deficiency diseases on a basis of polyglandular pathology. The book contains an interesting but rather sketchy chapter on the history of the study of the endocrine glands, in which, by the way, no mention is made of Cannon, Crile, or Sajous. The reciprocal relations of the various glands, the tests of endocrine reaction, and general organotherapy, among other topics, are considered in the general part. In the special division the author takes up, in turn, Graves's disease, myxedema, endemic cretinism, tetany, presenile involution, adiposity, cachexia hypophyseopriva, acromegaly, gigantism and nanism, diabetes insipidus, osteomalacia, Addison's disease, osteopsathyrosis, status thymicolymphaticus, and finally, the gonadal dyscrinisms. The photographs of illustrative cases are particularly good.

DIABETES

The Treatment of Diabetes Mellitus With Observations Based Upon Three Thousand Cases. By ELLIOTT P. JOSLIN, M. D. Third Edition, Enlarged, Revised and Rewritten. Illustrated. Philadelphia and New York: Lea & Febiger, 1923.

Verordnungsbuch, und Diätetischer Leitfaden für Zuckerkranke. Mit 149 Kochvorschriften. Von Prof. Dr. CARL VON NOORDEN und Prof. DR. S. ISAAC, in Frankfurt am Main. Berlin: Verlag von Julius Springer, 1923.

The subject of diabetes mellitus and its treatment with insulin is still in its infancy and is undergoing changes from day to day. The author has brought forth a book which enables the physician to know almost at a glance how to treat any feature of diabetes with which he may meet. Even though advances in knowledge are expected, this book deserves a hearty welcome to guide the physician through all the intricacies of the disease. It is an excellent summary of our present knowledge at this moment. The innovations, in this the third edition, are the chapter on insulin therapy and the sections on pathology, respiratory metabolism, levulose, duodenal ulcer, diabetes of twenty years' duration, the Newburgh and Marsh methods, and the modern conceptions of acidosis. The insulin treatment in the home is of particular interest to the general practitioner. Bailey's tables of diabetic and nondiabetic foods are of inestimable value. The Harris and Benedict tables for predicting the metabolism are very clear. The technic of the treatment outlined and the test and maintenance diets simplify the therapy considerably. The time honored treatment of diabetic coma without the use of alkalies or excessive carbohydrates is discredited. The subject of surgery in diabetes is treated in great detail. The bibliography, including English, German and French literature, is complete and up to the minute as late as May, 1923. A great many case reports are cited and their progress is noted up to the time of publication—November, 1923. The style is delightful and straight to the point. It proves most interesting reading and one almost feels regret at ending a chapter. To the physician who wants to know all there is to be known about diabetes mellitus and its treatment at the present moment this book is invaluable and indispensable.

* * *

This is the seventh edition of a little pamphlet that was originally prepared by Carl v. Noorden and E. Lampé and intended for distribution among diabetic patients in their private clinic. It has been thoroughly revised and extended. The subject matter deals exclusively with the diet of the diabetic patient. Although certain dietetic courses are advised, the physician himself should individualize the prescribed diet to suit each individual patient. About one hundred and fifty recipes for the preparation of foods are given in detail. The manufacturers of certain diabetic foods are also mentioned. This little book may be used by both physicians and patients, but the diet should always be supervised by the physician to suit the varying conditions requiring treatment. The tables of food substances give the food values and constituents, not as they occur in the raw state of the food, but as they are available and their amount, which is of great assistance in the calculation and prescription of the diet. The work is based on an experience of twenty-eight years in over twenty thousand patients and serves its purpose admirably.

COLLOIDS

The Colloidal State in its Medical and Physiological Aspects. By SIR WILLIAM BAYLISS. Oxford Medical Publications. London: Henry Frowde and Hodder and Stoughton, 1923.

No one is more competent than Sir William Bayliss to present to an English audience those interesting and obscure problems concerning the relationship of matter, when one phase is in the solid, the other in the fluid form. There is a great deal of extremely loose talk among medical men and even biologists concerning the immense importance of the colloidal state, and the explanation of the nature of living substances, but when one reads even so limited a presentation of the subject as this little book of Bayliss's, it is very evident how great are the lacunae in our knowledge and how important further researches are. While not replacing any of the standard works on colloid and interfacial phenomena which have appeared in German in the last few years, this volume is the best short survey of the subject in the English language.

COLLOIDS

Pharmacodynamie des Colloides. Choc, Pathologique et Therapeutique. By W. Kopaczewski. Paris: Gaston Doin, 1923.

Much interest has centered around the discovery in recent times of the fact that colloidal suspensions of indifferent substances such as kaolin produce symptoms resembling those of anaphylaxis. A restudy of the whole subject from the point of view of colloid chemistry is now in order. The writer of this small volume has collected in a convenient form much of the information which has been published on the subject, and for those who read French, it will prove of interest. The physician who is endeavoring to obtain some practical hints as to the treatment of his patients may well avoid the labor of its perusal.

THYROID SURGERY

Le Sympathique, Cervico-thoracique. By Thomas Jonnesco. Paris: Masson & Cie, 1923.

This is one of the most beautiful books that has even been brought out on the anatomical and surgical considerations of the sympathetic in the neck region. It contains thirty-four figures and ten colored plates of exquisite workmanship. The region considered is of special importance in reference to thyroid surgery. Many technical operative procedures are explained in detail. This book should prove extremely popular in this country.

INTERNAL SECRETIONS

Les Sécrétions Internes. By Maurice Perrin and Alfred Harns. Paris: J. B. Bailliere and Fils, 1923.

This second edition should be welcomed as it comes at a moment of intense interest in matters concerning endocrinology. The attack here is primarily that of the influence which the endocrine glands have on the blood. In the light of our present knowledge, the work is well handled, only the most acceptable hypotheses being considered. The various glands are taken in turn and then a general résumé is given of their interrelationship. The book fills a distinct need in the field of endocrinology.

ASTHMA

Asthma. By Frank Coke. New York: William Wood & Co., 1923.

It was indeed a profitable pleasure to read Dr. Coke's recent book in which asthma and hay fever are treated clearly and concisely. Coke presents a new classification of asthma, which seems to be very satisfactory; it is certainly as practical as the other classifications that have been used.

Case reports on pages 165 and 166 are interesting, but, perhaps, somewhat over optimistic. The failures in the treatment of asthma and hay fever are not given the emphasis that their unfortunate frequency warrants. The wisdom of adding the term adzyme to our already overstocked list of immunological terms might be questioned. Will it not have a tendency to increase our present confusion? On page 35 Coke states that it is rarely necessary to make a control test, except in those cases where we are testing the sensitiveness of high dilution. In the opinion of the reviewer it is essential to make a control test in every case. Many patients have hypersensitive skins, so called dermatographic skins, and react positively to all scratch tests. It is unfortunate that so little space has been devoted to pollen sensitization, since it is so prevalent in this country. Coke gives excellent reasons for the occurrence of late sensitizations, particularly to feathers. Several cases are cited of sensitization to human hair. This is most interesting and highly important. It deserves careful study.

Coke's results with bacterial skin tests have been more encouraging than is usual. As a rule there have not been very good results with bacterial proteins in skin tests. While we may not agree with Dr. Coke in every particular, yet he has contributed a timely and valuable addition to medical literature.

THE LARGE GUT

Diseases of the Rectum and Colon and Their Surgical Treatment. By P. Lockhart-Mummery. F.R.C.S. Eng. New York: William Wood & Co., 1923.

Civilization leads to many disturbances of the alimentary tract and more especially of the lower portion of this organ, namely, the colon and rectum. Foods are usually given in pure form, divested of all indigestible material and a sedentary life is more common. These two factors make affections of the bowels more frequent. Lockhart-Mummery's present excellent work is written with the object of helping physicians combat successfully the diseases of the colon and rectum. The question whether the colon is a useful organ the author answers in the affirmative. "There has recently been much dispute," he says, "as to the value of the colon, and there are not wanting those who maintain that we should be better and healthier if we possessed no colon. The fact that human beings can live without a colon is, however, no proof of its uselessness, and at present the evidence brought forward to prove that the colon is a useless and effete portion of the alimentary tract is anything but convincing. Under conditions of modern civilization, it is undoubtedly possible for human beings to live without a colon, and perhaps even for it not to be missed; but man was not designed to live in a London flat, with servants and a banking account, and this can hardly, therefore, be taken as an argument that the colon is useless."

Lockhart-Mummery is not an advocate of colectomy. He says: "Sir Arbuthnot Lane has found, after resection of the entire colon, that the patients suffer severely from vomiting, which in several cases has threatened to end fatally; this can be prevented by subcutaneous infusion of water. It is, I think, evident that the loss of body fluids resulting from total exclusion or excision of the colon may seriously interfere with health, and this loss cannot entirely be compensated by an increased intake of fluid by the mouth. Further loss of health from that cause may not be evident for a long period after operation. It would seem that it is not the loss of fluid alone, but of some other constituent of the intestinal contents absorbed or reabsorbed by the colon which interferes with the patient's health."

The author lays great stress on a digital examination. In ulcerative colitis, Mummery advocates an early appendicostomy, especially in the severer form of the disease. He considers the prognosis of ul-

cerative colitis as bad unless an operation is done. The purpose of the appendicostomy is to establish efficient flushing of the colon through a tube introduced through this new opening into the colon. Mummery does not seem to be aware that this can be done without operation by introducing an intestinal tube through the mouth and permitting it to reach the cecum—a procedure which has been described in the New York Medical Journal.

There is a special chapter devoted to diverticulitis of the colon. The book abounds in fine illustrations and contains rich and useful information on the handling of the diseases of the rectum and colon. It is certainly one of the best books written on this subject and deserves a prominent place in the physician's library.

BACTERIOLOGY

Leitfaden für die klinisch-bakteriologischen Kulturmethoden. By Dr. Hugo Schottmüller. Berlin-Wien: Urban and Schwarzenberg, 1923.

This little volume of under a hundred pages contains an excellent survey of the current technic for bacteriological study of the blood. The methods given are largely those developed by Schottmüller and his German coworkers. Little or no attention is paid to the important contributions which have been made from this country. Within these limitations the work is complete, and offers a useful guide in bacteriology.

NURSING MANUAL

An Introduction to Applied Psychology for Nurses. By Donald A. Laird. Illustrated. Lippincott's Nursing Manuals. Philadelphia and London: J. B. Lippincott Company, 1923.

Nurses will find here a book full of practical interest as it is stimulatingly instructive, for it vitally represents life just as it occurs. It presents to the nurse a field of observation within herself and gives aid through enlarged understanding in dealing with her patients. It presents psychology as nothing more nor less than the study of the organism in its problems of reaction to the environment. The author discusses the nervous system as a functioning mechanism which the organism has evolved for itself to permit the necessary reactions, but only as one part of that larger mechanism which includes also the physicochemical cell and the glandular systems. He shows that the complicated psychic life has grown up upon a basis of interrelation of these various functional capacities. He traces in brief some of the complexities of emotion and thought which utilize these mechanisms and which in turn are dependent upon them. These are the moods, temperaments, distinct mental aberrations, or the more ordinary forms of behavior to be found in the patient or in the nurse herself or others in the environment. Thus psychology is given a fundamental physiological and biological foundation, while the psychic aspect is not neglected. One might complain of too great brevity in regard to the actual mental content, particularly in the unconscious, which motivates various special conditions enumerated. This brevity however, in part is compensated for by the suggestiveness both in the matter and in the method of presentation. There is at least sufficient reference to the range of mental content and mechanism to stimulate further inquiry.

EXERCISE

Exercise for Health and Correction. By Frank D. Dickson, M. D., and Rex L. Diveley, M. D. Philadelphia and London: J. B. Lippincott Company, 1923.

The authors state in their preface that this book was written with but one purpose in mind—the giving to those interested in the building up of their bodies a brief but fairly complete and systematic manual of exercise. To this end the number of exercises included was reduced to a minimum, and many purposely omitted, for instance, those used in the treatment of scoliosis and curvature of the spine, since these can be successfully employed only under the direct supervision of a trained instructor and so would be out of place in a work intended largely as a guide for selfinstruction.

The exercises are arranged in a series of five groups. The first two groups are designed to tone up the muscles of the body as a whole and to improve the general health. The three latter apply to special conditions that are moderately prevalent and that may be remedied by training of the muscles. Groups 3 and 4 include exercises valuable in treating faulty carriage and visceroptosis. Group 5 applies to conditions in which lack of muscle balance in the foot is present, such as flatfoot and fallen arches. A special feature of the book is the excellent illustrations, all made from photographs to show exactly the execution of each movement.

A brief introduction emphasizes the value of the proper attitude of mind, attention concentrated upon the business in hand, a clear understanding of the various movements of each exercise, and exactness of execution. Although the book is written for the layman, physicians and nurses and physical directors should find it of value, particularly in advising or prescribing home work.

PSYCHOLOGICAL FICTION

Round the Corner. By Gilbert Cannan. New York: Thomas Seltzer, 1923.

Annette and Bennett. By Gilbert Cannan. New York: Thomas Seltzer, 1923.

It was our good fortune to happen upon *Round the Corner* after reading its sequel *Annette and Bennett.* Questions of behavior, character, environment, surmised from the latter volume, are here verified. We meet Annette and Bennett in the making, follow breathlessly the very near engulfing of Bennett in a mother fixation vortex. The strain of James Lawrie that proves the salvation of all the sympathetic characters in this series of Mr. Cannan's, is hinted at here, but is not quite the *deus ex machina* that it is in *Annette and Bennett.* Probably there is an earlier volume to tell us how James Lawrie himself was captured, flayed and garrotted, but we have not yet come across it. Mr. Cannan has analyzed and interpreted all these friends of his in a way that leaves room for no improvement. We should like to see what he has to say about the fatal fascination that holds old Lawrie bound to his drink-shod, hag-ridden nights and days. Bennett escapes the ghoulish mother (thanks to the Lawrie in him plus Annette); his son who figures in the later volume escapes also by virtue of the same combination. What then has got into the bones of the ultimate hero?

Round the Corner shows a milder form of domestic infelicity than that of the Lawrie household. Yet it is, perhaps, just as deadly a picture for it combines with its internal bitterness, hypocrisy. At least the hate is in the open at Lawrie's. The Folyats—(is it because Mrs. Folyat is so imbecile, or should the sin really be laid at the door of a generally imbecile society?)—the Folyats are an ideal family—to outsiders. Such lovely people!

Now we are going to read *Annette and Bennett* again to catch up further developments among all these newly met characters, and then perhaps we shall turn once more to *Round the Corner,* to savor the beginnings of lives that are as real to us as our own.

Medicoliterary Notes.

Some interesting vital statistics for Prussia have recently been published by the government of that country. The figures include data covering the years 1912-1921. It may be of interest to quote a few of these. The population of Prussia in 1912 was estimated to be 41,300,000; in 1921, it was 38,300,000. Suicides recorded in 1912 amounted to 8,793; in 1913, to 9,214; in 1921, to 7,559. The number of births in 1913 was 1,173,416; in 1921, they fell to 968,768. Deaths from excessive indulgence in alcohol were 936 for 1912; 913 in 1913; 155 in 1920, and 297 in 1921. Before the war, the number of divorces amounted to from 4,000 to 9,000 each year; in 1919 this number increased to 13,261; in 1920 to 23,059; and in 1921, to 25,836.

* * *

Barnum, by M. R. Werner, is one of the most interesting and entertaining biographies of the year, and valuable besides as a study of the psychology of "the prince of humbugs," which the great showman was pleased to call himself, as well as of the psychology of the crowd, especially the American one.

* * *

Chicago is making a fight against the smoke nuisance. It was one of the first American cities to combat this nuisance, the first smoke ordinance having been passed in 1881. A recent issue of the *Weekly Bulletin* of the Department of Health is devoted to telling how this fight has been carried on since 1881, with suggestions and advice as to how householders, landlords, janitors, etc., can give practical help, and at the same time save fuel, by running their heating plants properly.

* * *

Maurice Maeterlinck, Jane Cowl and Rollo Peters have combined in presenting a very charming and beautiful entertainment for the theater goer in the current production of *Pelléas and Mélisande.*

* * *

A Preface to Life, by Edwin Justus Mayer, recently brought out by Boni & Liveright, is the autobiography of a New York City youth who has been already in his short span of life a salesman, a peddler and a press agent, yet has had—or made—time for much fun, plenty of reading, outdoors, wholesome self study, and many of the other pleasures and benefits of life popularly supposed to be nonexistent for the individual who holds a real job in the daily grind of the Great City. Perhaps early experience in the business world, coupled with an intelligent and wholesome interpretation of that experience led to wisdom. We gather this from what Mr. Mayer writes: "At fifteen I began a journey encumbered with a lot of useless and false data concerning the history and aims of Man. . . . So utterly nonsensical were the notions I held—in common with most boys—regarding the validity of current formulas of success, that my first adventures among jobs were sufficient to knock those long accumulated notions clear out of my head."

* * *

Among books on medical subjects recently published are *Walking for Health,* by Dr. Alvah H. Doty (Appleton), and *Vitamines; A Critical Survey of the Theory of Accessory Food Factors,* by Ragner Berg, a German authority (Knopf). A new publication from the University of Chicago Press is *Protoplasmic Action and Nervous Action,* by Ralph S. Lillie.

* * *

Dr. Haven Emerson, writing in the *Nation's Health,* states that in a study of the records of heart patients of ten hospitals in New York City for twelve months in 1920, and in some cases in 1921, it is shown that in not less than 4.58 per cent. of all admissions to general hospitals the patients were suffering from heart disease of a seriously disabling degree; 9.35 per cent. of all days of bed care provided were required for these cases.

* * *

Adventures in Silence is the title of an interesting autobiographical work by Herbert W. Collingwood, a man who through forty years gradually became deaf. He relates his experiences on "the road to silence" and tells of his life after hearing was completely gone. The purpose of the book, the author states, is to furnish a sincere personal record of the life and psychology of the deaf, with a view to helping others so afflicted to attain the sane and, to an extent, successful sublimation reached by himself.

* * *

A method of preventing propagation of mosquitos that has been tried out both in Panama and in Germany is the growing of water plants capable of excluding air from the larvæ. Several plants have this capability, but one that can do it most attractively as well as efficaciously is the *Azolla Caroliniana,* a water fern with leaves so small that their structure, to be perceived, must be studied through a microscope. When thus examined, minute air bubbles are perceptible, supporting the plant on the water so that the upper surface is kept quite dry. Mats of *azolla* float on the water, resembling beautiful rugs woven from red and green strands. It is these mats that by excluding the air, are death dealing to the mosquito larvæ. The *azolla* multiplies with great rapidity because it reproduces not only by spores but also by direct budding from the parent cells.

Practical Therapeutics

ENDOCRINE THERAPY

By J. T. Wright, M. D.,
Mayview, Pa.

From articles by Lewellys Barker, Cohoe, Litchfield, Hoskins, Bandler, Hoxie, Banting and others, I present a few of the findings and indications for the therapeutic use of endocrines, so far as known, to present date.

Endocrinology has assumed almost a special field of medicine, and much study, thought and experimentation have been expended by clinicians and laboratory men in an endeavor to learn Nature's secrets in this mysterious realm, and apply the same to the relief or cure of disease, and recently the brilliant results achieved by Banting with his product of the pancreas (insulin) in the treatment of diabetes has stimulated further study and research, which we trust may be richly rewarded. However, no fixed principles have as yet been established concerning the physiology of the endocrine glands, and present day endocrine treatment has developed empirically by trial and experimentation; for as yet only three hormones have been successfully isolated—epinephrin, thyroxin and insulin; the latter recently.

The obvious aim of any form of endocrine therapy should be to restore the patient with demonstrable endocrine dysfunction, or imbalance, to a state of normal functioning of the incretory glands, and theoretically this might be accomplished in three ways, viz., increasing, modifying, or decreasing the functional activity of these glands. In cases of hyperfunctioning surgical intervention may be resorted to and excision of the gland may be undertaken, as in goitre, or the arteries ligated. Also radiotherapy may be used with benefit.

Where there is hypofunction transplantation of a homologous gland may be attempted, or therapy by administering the gland extract or hormone, either by mouth or hypodermically. One of the obstacles to organotherapy is the variability in the preparations of gland products and of the doses employed. They should be standardized. Also there is variability in the reaction of patients to any given hormone. Hoskins has pointed out that in the case of epinephrin the vasomotor reactions may be diametrically opposite, depending on the initial blood pressure, vitality, temperature, dose and on depth of anesthesia when used as a heart stimulant.

Pituitrin may act variably also, depending on the condition of tone of the responsive mechanism at the time. Neither do we have any definite knowledge of the fate of the gland extracts or hormones in the alimentary tract when administered by the mouth, or how much they may be absorbed. Nevertheless, I have seen marked improvement in cases of neurasthenia, and in a few cases of dementia precox (catatonic), which resulted from organotherapy, combined with protein rich diet, hydrotherapy, diversion and hygienic living.

Carlson has pointed out, however, that endocrine therapy can hardly have effect on conditions due to dysfunction of the ductless glands that function on the principle of detoxication; or on glands which furnish incretions, where the hormones are not stored up in the gland, or cannot be chemically isolated; or where they are destroyed by digestion after oral administration. However, this is no reason for not trying, or for pessimism, as means and methods may be learned and used successfully as our knowledge increases and research progresses.

The brilliant results obtained by Horsely, Murray *et al* in the treatment of myxedema; and of pituitrin in obstetrics and in postoperative tympany and flatulence, justify all the labor spent in an effort to evolve or create a definite endocrine therapy for other conditions—not to mention the recent epoch making discovery of Banting and associates of insulin and its marvelous effect in controlling the sugar output in diabetes mellitus. Lately also much has been written of the action of epinephrin (adrenaline) injected into the heart muscle as a means of resuscitating the apparently lifeless, after drowning, prolonged anesthesia, severe syncope, etc. So it would seem this field offers a brilliant future to earnest, scientific investigators.

To mention a few of the clinical applications of organotherapy it is only necessary to add a few items. It has been shown that thyroxin, which was isolated by Kendall in 1914, is a general body cell stimulant, that it is present in a definite amount in the tissues of the normal body, and that a full dose administered to a thyroidless person is not fully exhausted until the sixth to eighth week, and that a small daily dose will hold the basal metabolism of the patient within normal limits. Thyroid extract has been used in myxedema, cretinism, obesity, chlorosis, enuresis, certain cases of epilepsy, eczema, psoriasis and sterility; the basal metabolism rate being a criterion for its dose. Lately it has been shown that at least three other glands, the suprarenal, the anterior lobe of the pituitary and the gonads, influence metabolism.

Tethelin, isolated by Roberts in 1916, is supposed to be the active principle of the anterior lobe of the pituitary, but it has not yielded thus far any remarkable results and is probably not a true hormone, but extracts of the anterior lobe have been tried with variable results. The active principle of the posterior lobe pituitrin, however, is known to be one of the most powerful stimulants and contractors of unstriped muscular fibres, given hypodermically. It has been used in obstetrical practice, shock, certain types of epileptiform convulsions, where the gland is diseased, with good results; in impotence, dementia precox with probable endocrine basis; baldness and other conditions. In Addison's disease treatment by suprarenal extract has been insufficient and disappointing. In low blood pressure and neurasthenia it has given results, and recently it has been found that there is a relative functional insufficiency of the suprarenal cortex in exophthalmic goitre, and fresh ox suprarenal cortex fed to patients raw who had exophthalmos caused a rapid increase of weight and much strength, though the pulse rate was not changed. Epinephrin has the same effect in stimula-

tion of the sympathetic nerves and is useful in asthma, shock, cardiac syncope, edema of the larynx, urticaria, anaphylaxis, hay fever, and other conditions. Regarding the gonads, corpus luteum has been used in vomiting of pregnancy, menstrual disorders, climacteric disturbances and hypertensive states. Ovary and testicle extracts have been used in osteomalacia, as invigorators; and gland transplantation in impotency and senility with temporary results. The pineal gland seems to be in some way essential to the growth and development of the child, but no results have followed its administration. The thymus gland is as yet little understood, but is essential to child life. The prostate gland and its secretions are being studied, as well as the lymphatic ganglia, the spleen, the internal secretions of the liver, and we hope soon to have further knowledge of these interesting organs and their connection with the mysteries of life, heredity, mentality, etc. As some one has said, "We are the product of our glands."

SOME CONSIDERATIONS OF BLOOD PRESSURE DISORDERS, THYROID HYPERTENSION, AND ADRENAL HYPOTENSION

By Henry R. Harrower, M. D.,
Glendale, California.

The present day interest in the study of the endocrine glands has opened up some very fascinating possibilities in the control of functional irregularities in the blood pressure. Since the advent of the sphygmomanometer, it has become quite the thing to estimate the blood pressure in practically all classes of puzzling cases, with results which can only be considered an advantage to all concerned.

Of the two great classes of irregularities in the arterial tension—the functional and the organic—the former particularly will be given some consideration at this time. This form of high tension is sometimes called essential hypertension, while others term it primary or benign hypertension. Organic blood pressure changes rarely have an endocrine aspect of importance and we shall not consider them now.

Essential high blood pressure is common enough in certain types of patients, but my personal opinion is that this disorder is far less frequent, and also less easily controlled, than a reduced blood pressure. Let us consider the problem of functional hypertension from an endocrine viewpoint and see if it does not open up to us some interesting therapeutic prospects.

In Sir Humphrey Rolleston's recent paper (1), he remarks that "it must be admitted that of the cause or causes of simple permanent high blood pressure we really have no exact knowledge." Yet I think that we are learning something which will dispel this ignorance. The thyroid gland is known to exert an important and decisive control over cellular chemistry. Studies of thyroid insufficiency ranging from the minor and insignificant forms to the major type, such as myxedema, convince us that one feature is preeminently important, because it is invariably present—I refer to the condition called by Dr. Eugène Hertoghe, of Antwerp, infiltration. The philosophy of this is briefly explained as follows:

The thyroid gland exerts a stimulating effect upon the cellular metabolism. Conditions which reduce the thyroid efficacy also lessen the metabolic rate in the cell, with a consequent accumulation of wastes, which must clog up the entire mechanism. The accumulation of these half oxidized, poisonous waste products in the cells naturally causes a physical reaction which is based upon the fundamentals of osmosis. The intracellular tension is increased, merely because there is a larger amount of these substances in solution. As a result of this, an increased amount of fluid is drawn to the cells from the surrounding lymph in order to make the specific gravity of the cellular contents equal to that of the surrounding fluids. This actually swells out the cell and as a result, the condition of infiltration is started. Without a doubt, this is just what takes place in varying degrees in all the cells which are influenced by the thyroid hormone and, as far as we know, practically all parts of the organism are influenced thereby.

There are many clinical aspects to this matter of thyroid infiltration. Hertoghe and many other writers have emphasized its various phases in a number of papers. I now propose to call your attention to an aspect of this subject, which relates the thyroid to high blood pressure. Without a doubt, the infiltration of millions of cells in the remote and so-called precapillary areas brings about, in the aggregate, a serious interference with the circulation, which cannot but cause an increase in the tension. The heart discovers that it has a greater opposition than heretofore to its efforts to force the blood through the capillary circulation in the extremities of the body. As a result of this the left half of the heart, in particular, works harder and more strenuously, thus increasing the tension. Thyroid insufficiency favors a mechanical interference to the circulation in the precapillary areas and a functional high blood pressure is thus brought about. Quite the best evidence of this is the fact that the stimulation of the cellular chemistry by the only rational means under the circumstances, that is, thyroid therapy, gradually reduces this infiltration and with it, not merely many symptoms of hypothyroid origin known to be based thereon, but also frequently reduces the blood pressure. For many years there have appeared in clinical literature occasional hints that thyroid in suitable cases was a depressor remedy, small doses sometimes reducing, in a comparatively short time, an increased blood pressure by thirty or more millimetres.

There are some other aspects of functional high blood pressure that relate to others of the endocrine glands. The adrenals must be involved in certain cases, for the well known toxic and emotional features of certain hypertensions are far too common to be more than a suspicious coincidence.

Again, a number of gynecologists have found that, in women at the climacteric there occurs a temporary hormonic rearrangement, which sometimes is associated with considerable increases in the blood pressure, which are mitigated by a modification of the hormone irregularities of this period. As to whether climacteric hypertension is purely of ovarian origin, and whether there is not also a thyroid feature to it,

I can only say that hyperthyroidism is very much more common in women; and that those who have studied the statistics carefully, say that ninety-five per cent. of the cases of myxedema in women occur in the decade between forty and fifty.

Now, a few words regarding hypotension. It is an exceedingly common feature of many diseases. Sir Humphrey Rolleston says in this connection: "In most acute infections the blood pressure is lowered. Diphtheria shows a well marked fall of blood pressure; in scarlet fever the lowering of the pressure is much less than in diphtheria and enteric fever[1] . . . Tuberculosis is generally regarded as characterized by a low blood pressure, and so on."

The marked asthenia of the postfebrile state or of the toxic individual, effects the tonicity both of the cardiac musculature, and of all unstriped muscle, including that of the bloodvessels. Hence a low systolic tension is to be expected in a large number of conditions, acute or chronic. The cardiovascular aspects of these fatigue syndromes very often include hypotension. In fact, the late Dr. Alfred Martinet, of Paris, referred some years ago to a circulatory syndrome related to minor adrenal insufficiency, which he aptly termed hyposphyxia which consists essentially of poor circulatory tone, cold extremities, venous stasis, and, naturally, a low blood pressure. Persons with the fatigue syndrome and hyposphyxia have so uniformly been affected by some adrenal depleting condition—toxemia, undue fatigue, or emotional stress—that the search for other features of hypoadrenia usually is rewarded by uncovering further evidence relating the circulatory picture to the endocrine.

Functional hypoadrenia is a most common cause of functional (systolic) hypotension, and both the cause and the extent of its effects differ from the real Addisonian disease only in degree. In other words, hypoadrenia is a minor or functional inadequacy; and it is well known how marked and pathognomonic is the circulatory disorganization in actual adrenal disease.

Quite the most interesting and convincing feature of functional hypotension is the facility with which it responds to a therapeutic measure which I have called adrenal support—an organotherapy calculated to encourage and reestablish adrenal activity. To my mind such responses are as confirmatory of the original basis of the pressor difficulty as are the benefits derived from thyroid therapy in hypothyroidism. In fact, the endocrine features of functional hypotension, as well as those of functional hypertension previously referred to, have the very great advantage of serving us in a diagnostic way, just as their application benefits our patients from a therapeutic standpoint.

The physician who has made blood pressure studies in several hundred cases undoubtedly has learned that one interesting feature of a functional blood pressure irregularity is the fact that the diastolic readings are not so seriously altered; or, in other words, that functional blood pressure changes usually involve the systolic pressure only. The pulse pressure, i. e., the difference between the intravascular tension during the period of heart rest (diastole) and the ventricular activity (systole) naturally is increased comparatively more in such functional disorders, since organic conditions which cause an increased diastolic pressure may not cause so great a systolic rise with a corresponding variation in the difference between these figures. At any rate, I have found that functional, noncardiac, nonsclerotic, and nonrenal increases in the blood pressure usually become systolic in time.

If the two dissimilar blood pressure conditions may be due to hypothyroidism on the one hand, and hypoadrenia on the other—and general endocrine derangement usually is pluriglandular in character—why may not the hypertension due to hypothyroidism be neutralized by a coincident hypotension due to hypoadrenia? Undoubtedly, the answer is that it may be; and right here is one of the advantages of the relation of the endocrine glands, since the blood pressure conditions due to hypothyroidism and those due to hypoadrenia, in a degree, offset one another. This is also one of the complicating factors from a diagnostic point of view.

When a suddenly acquired hypotension manifests itself, systolic in time, and with an etiology such as I have mentioned, obviously the adrenal feature predominates; while if there is a gradual increase in the systolic tension with coincident evidences of the infiltration expected from hypothyroidism, the thyroid disorder is presumed to predominate.

Pluriglandular treatment directed at a thyroadrenal inefficiency may not affect the blood pressure so much—at least the thyroid which we may give will not reduce the pressure unless the mechanical infiltration factor is present—and it may be said also that thyroid may be given in cases of hypotension with much more impunity than can adrenal substance in cases with really high systolic pressure.

[1] Possibly due to a mechanical factor in the kidney—renal involvement is very common in scarlatina—which tends to maintain the tension.

THE INTRAVASCULAR USE OF GENTIAN VIOLET

By H. Mooser, M. D.,
and P. W. Monroe, M. D.,
City of Mexico, Mexico.

It is the purpose of this article to report briefly on the use of gentian violet intravenously in several cases of systemic infection, proved or suspected of being caused by Gram positive organisms. These cases are taken from the private practices of several physicians. Most of them were treated in the American Hospital of Mexico City.

During the spring and summer of 1921, Dr. Mooser, pathologist to the hospital, repeated some of the experiments of Bresgen, Stilling and Wortmann, reported by Bauman (1), and of Churchman (2), demonstrating the bactericidal action of this dye. Also he injected guineapigs and rabbits with solutions of gentian violet and observed them for toxic symptoms. No such symptoms were noted. A white rabbit of two kilos weight, injected through a vein of the ear with two c.c. of a one per cent.

solution, giving a strength of one to one hundred thousand of body tissue, became cyanotic for about twenty minutes; it sneezed and became cold, but would continue to eat. Ten minutes after injection, the serum showed a slight bluish tinge, and one hour afterward the animal was entirely normal.

While these experiments were in progress, Dr. Mooser suggested the injection intravenously of gentian violet in a desperate case of sepsis then in the hospital. (Case I.)

The gentian violet used was prepared for injection by dissolving in sterile distilled water, filtering, and boiling in a water bath for ten minutes, a fresh solution being prepared for each injection. For some of the injections, solution was first made in one or two grams of alcohol and the water added. Ten or fifteen c.c. of a one per cent. solution is the amount commonly used (in cases reported below solutions were of this strength unless otherwise designated), although twenty c.c. of approximately a two per cent. solution has been given. The solution is injected from an all glass syringe as is neosalvarsan and at about the same rate. A too rapid injection may be followed by some thickening of the vein, and any of the solution outside of the vein sets up a considerable irritation in the adjacent tissues. As the drop of blood cannot be seen if drawn back into the gentian violet solution, I have found it convenient to use the ordinary hypodermic syringe, empty, with a small calibre needle attached for insertion into the vein. This syringe may be filled with blood for culture if desired, disconnected from the needle, and the larger syringe of gentian violet attached. A two per cent. solution of oxalic acid readily removes any stain and cleanses the syringes.

During and for several minutes following the injection there is slight cyanosis. Chills have occurred after about half an hour, and some fever. The majority of the injections have not been followed by reactions. The urine shows no discoloration or evidence of kidney irritation.

CASE HISTORIES.

Case I.—(Dr. Ulfelder). Mr. R., American merchant, aged forty-five, admitted March 21, 1921. The complete record of this case is not of interest in connection with this article. He gave a history of gallbladder trouble of long standing. He had refused operation, but on March 29th, the gallbladder and an abscess surrounding it were opened and drained. He did not do well, but continued a typically septic course complicated by a bad heart. April 9th, temperature 102°, pulse 120—twenty c.c. of gentian violet were given without any noticeable effect. Blood culture gave both colon bacilli and streptococci. April 11th, temperature 101°, pulse 130—twenty c.c. of gentian violet. The man continued to grow worse and died on April 16th.

Case II.—(Dr. Prestley). Mrs. F., Mexican, aged twenty-seven, admitted April 10, 1921. (The chart and record of this case have been lost. These notes are made from memory.) Ten days before admission she had a normal delivery at home, attended by another physician. Two days later she had a chill and fever. She became very ill, delirious, and unconscious, temperature 105°, pulse 120 or more. On admission she had an eruption resembling initial rash of smallpox, leucocytes 28,000 (no increase in mononuclears, the eruption assumed characteristics of serum rash). Fifteen c.c. of gentian violet were given on day of admission. April 11th no fever; pulse still rapid, moderate thrombosis of femoral vein. April 12th, ten c.c. of gentian violet. Continued improvement until discharge May 8th.

Case III.—(Dr. Bokendahl). Mrs. A., Polish, aged forty-four years, admitted June 18, 1921. Two days before admission she had an incomplete abortion, induced by herself. On admission her temperature was 103°, pulse 108, and she complained of chilliness and pains in abdomen. A dead fetus was removed. On the four following days she had repeated chills, temperature 100° to 103.2°, pulse 90 to 140. June 22nd, ten c.c. of gentian violet were given. June 23rd, temperature 98°, pulse 86—ten c.c. of gentian violet. After June 26th the temperature did not go above normal nor the pulse above 90. Discharged July 6th.

Case IV.—(Dr. Prestley). Mrs. P., Greek, aged twenty-four, admitted February 1, 1922. On January 28th, she had had a normal delivery, attended by another physician in her home. The placenta was removed by hand. On January 30th, she had a chill and temperature of 103°. Blood culture gave Streptococcus hemolyticus. She was brought to the hospital restless and delirious, temperature 104°, pulse 152—ten c.c. of gentian violet given. February 2nd, temperature 103.2°, pulse 126—ten c.c. of gentian violet given. February 3rd, the temperature did not pass 100° or the pulse 108. She became maniacal. No further injections were given. She continued with slight irregular fever, rather rapid pulse, and symptoms of a depressive insanity until her discharge February 16th. On April 25th, the husband reported that she was quite well except for alternating periods of excitement and depression.

Case V.—(Dr. Bokendahl). Mr. S., a German machinist, aged thirty-eight, admitted January 15, 1922. Three days before admission he had lost the greater part of two fingers of his left hand in the cogs of a machine. He entered with wounds much inflamed, the fingers were amputated. On January 19th, temperature 103°, pulse 100, with lymphangitis, and arm much swollen. Smears and cultures of pus gave streptococcus. The arm was immersed in hot solutions, the wounds opened well and Bier's treatment used. During the five succeeding days the condition did not improve. Temperature 98° to 101°. On January 26th he had a severe chill, temperature 103°. January 27th and again on January 28th, he was given ten c.c. of gentian violet, followed in each case in half an hour by chills and temperature 103°. January 29th, ten c.c. of gentian violet, no chill. After this date there was steady improvement until discharge February 14.

Case VI.—(Dr. Ulfelder). Mr. R., Mexican, aged 40, admitted January 24, 1922. On the day before he had been run over by an automobile. On admission temperature 98°, pulse 84, left arm badly bruised and lacerated with extensive avulsion of skin. He was given antitetanus serum and wounds cleaned. He did fairly well until January 30th when temperature reached 103°. The wounds were badly infected, the smears showing streptococci. The fever continued and during the succeeding days he was

given several injections of antistreptococcus serum. February 6th, temperature 102.4°. Blood culture gave hemolytic streptococcus—fifteen c.c. of gentian violet. Chill. February 7th, temperature 102.8°, but thereafter he had little fever and steadily improved until his discharge March 28th.

Case VII.—(Dr. Bokendahl). Mr. S., German, clerk, aged thirty-four, admitted February 19, 1922. Three weeks before admission he had an otitis media followed by severe nephritis. On admission temperature 102°, pulse 88, drowsy, marked general edema. The urine contained albumin, ten gm. per mil, blood casts, and streptococci. For several days the condition was little changed, temperature 100° to 102°, pulse 100 to 120, irregular. February 23rd—ten c.c. of gentian violet, repeated on February 24th. On February 25th there was more urine passed, albumin much reduced, less edema. From February 24th to March 1st, condition was fairly good, no temperature above 99.4°. March 1st, temperature 100.4°. March 2—ten c.c. of gentian violet. There was no fever for four days. March 8th, temperature 101°, pulse 120, poor quality, pain in left chest, dyspnea and cyanosis. March 9th, exploration of chest followed by rib resection and drainage. Many streptococci in smears, scant growth from culture. He did fairly well for several days but with gradually rising temperature. March 22, temperature 104.4°, pulse 144. An abscess was discovered between pleura and ribs. This was opened and drained—ten c.c. of gentian violet. Following this there was slow improvement, some fever, and a moderate nephritis. On April 15th he left the hospital, temperature 101°. He continued to improve and on May 10th was walking about.

Case VIII.—Mrs. M., Syrian, aged thirty-nine, admitted February 21, 1922. Three weeks before admission she had given birth to her fourteenth child. The labor was normal. She was attended by a midwife. Four days after labor she began having fever, chills, headache and general pains. These continued until admission. She had been given intrauterine douches. On admission temperature was 98°, pulse 84. Examination negative except for moderate uterine subinvolution. February 22nd, the temperature and pulse remained normal. February 23rd, temperature 103° and continued high through February 24th. She had a chill. February 25th, temperature 99°—ten c.c. gentian violet. February 26th, temperature 98°—ten c.c. of gentian violet. February 27th, chill, temperature 101.2°—fifteen c.c. of gentian violet. The next day she felt much better, temperature 98°, continuing normal until her discharge on March 8th.

SUMMARY.

The cases reported are from the experiences of several physicians, working independently of each other, therefore the histories and observations recorded have been difficult to compile and they are not as complete as could be wished. The experience of no single one of us has been extensive enough to admit of dogmatic opinion, but it seems that we are justified in concluding:

First, that the intravascular use of gentian violet is not seriously toxic, that it is practicable probably in larger doses than those we have used.

Second, that the behavior of some of these cases warrants the belief that we may have in it a therapeutic measure of great value.

Third, that these experiences seem to support the natural assumption that the blood infections without well developed and destructive foci in the tissues will be the most benefitted.

Treatment of Diabetes Mellitus with Insulin and Carbohydrate Restriction.—George Graham (*Lancet,* June 9, 1923) states that in order to get the best results it is unwise to give any carbohydrate at all, except that contained in vegetables, until the fasting value of the blood sugar has been below 0.12 per cent. for some considerable time. In order to produce this result, the blood sugar must fall well below 0.10, or even 0.08 per cent. each day in order to relieve the B cells of the islands of Langerhans of as much work as possible. It may be necessary to aid this by somewhat rigorous dietetic restrictions, or it might be achieved by giving larger doses of insulin. The advantage of this method is that only one dose of insulin a day is required, and the dose is much smaller. The disadvantages are: 1, the comparatively slow progress of the patient; 2, the careful watching of the blood sugar which is required, at any rate at the beginning of the treatment; 3, the necessity of lowering the blood sugar each day below 0.10 or 0.08 per cent., and so running some slight risk of causing unpleasant symptoms if the blood sugar falls too low; 4, the tendency of all patients with severe and long standing diabetes under severe dietetic restrictions to steal carbohydrates and so delay the fall of the blood sugar to normal.

Diathermy for Malignant Disease of the Mouth, Pharynx, and Nose.—On the basis of the results observed in seventeen cases, Norman Patterson (*British Medical Journal,* July 14, 1923) asserts that in cancerous growths in the larynx and mouth the ultimate results are likely to be infinitely better when the primary growth is dealt with by diathermy, rather than by a cutting operation. Complete block dissection of the glands in the anterior and posterior triangles should be carried out even when these glands are not palpable. It is generally advisable to destroy the growth in the first instance and to remove the glands subsequently. Occasionally the two operations can be carried out at the same sitting. If there is any doubt as to the ability of a thorough clearance of the neck, then the gland operation should precede that on the primary growth. If the glands cannot be dealt with it is little use applying diathermy to the primary tumor, except as a palliative measure. It is sometimes advisable to operate on the glands in the first instance, and to deal subsequently with the primary tumor, as consent for the neck operation may be difficult to obtain after the growth itself has been destroyed. Before commencing treatment, it is well to try and obtain consent for two or three operations, and to impress upon the patient the importance of the removal of the glands. If the diathermized area approaches or invades the fascial planes of the neck, a clear interval of a fortnight or three weeks should be allowed between the destruction of the primary growth and the neck operation.

Proceedings of Societies

SOUTHERN SURGICAL ASSOCIATION

Thirty-Fifth Annual Meeting, Held at Memphis, Tennessee, December 12 to 14, 1922.

The President, Dr. C. Jeff Miller, of New Orleans, in the Chair.

Very Large Renal Stone; Nephrectomy.—Dr. J. Garland Sherrill, of Louisville, Ky., reported a case which emphasized the contention so often made for the early removal of stones in the renal pelvis, kidney or ureter, because of the damage done to those structures by their long continued presence. There was possibly no pathological condition in which the diagnosis could be made with more accuracy, or in which relief could be provided with more certainty, than was possible in urinary calculi. There was, however, more difficulty in providing a treatment which would prevent their recurrence and very careful attention to diet, the ingestion of large quantities of water, and properly directed exercise, should be advised by the attendant.

Surgical Conditions of the Right Side of the Abdomen.—Dr. W. F. Westmoreland, of Atlanta, Ga., stated that the majority of these patients were not immediately cured by operation, the mechanical faults were corrected, but the rapidity of the convalescence depended upon intelligent medical care. All of these patients had acidosis, usually of a high grade. This acidosis was generally characterized by an acute fall and spring exacerbation and when an acid intoxication was present they felt very badly. Soda in sufficient doses to control the acidosis should be taken. The diet should not be restricted, but well balanced, with plenty of green stuff, fruit, particularly ripe oranges or orange juice. The patient should have plenty of sunlight and fresh air, preferably taken by light exercise in the open. The rapidity of the improvement in these cases was in proportion to the inhibition of acidosis, the well balanced diet, and the ability of the patient to take light exercise out of doors in the sunlight and fresh air.

Fractures of the Elbow Joint and of the Lower End of the Humerus.—Dr. Edgar Lorrington Gilcreest, of San Francisco, Cal., stated that for the treatment of fractures in the vicinity of the elbow joint, with the exception of fracture of the olecranon process, the fully flexed position offered the best results. Often a splint was unnecessary, the forearm being strapped to the upper arm and fixed to the chest with a bandage. The advantages of the flexed elbow positions were: 1, it gave the most complete anatomical reposition of fragments and the best fixation; 2, it favored the retention of the more important flexion function of the joint; 3, it cooperated with gravity in the subsequent restoration of function. In correcting the initial deformity the following procedures should be carried out: 1, strong traction was exerted on the forearm with the elbow fully extended and supinated; 2, at the same time, the joint was manipulated, the displacement being corrected as far as possible; usually the upper fragment would be found to be displaced forward and the lower backward; 3, then maintaining procedures 1 and 2, the elbow was slowly, but firmly, flexed to an acute angle and so fixed with the forearm supinated.

Strangulated Diaphragmatic Hernia.—Dr. Jere L. Crook, of Jackson, Tenn., said that there was a wide divergence of opinion as to the relative merits of approach. He believed the condition of the patient at the time he was first seen should determine largely our decision in this important matter. Where symptoms of strangulation and ileus were apparent the abdominal approach was an absolute necessity. Where the case was a chronic one, and the diagnosis had been clearly established and confirmed by x ray before operation, he believed the combined approach was indicated. From the experience gained in the case he reported he felt that every operation for the double operation should be made in advance, provided the diagnosis had been made in advance. The abdominal incision should be made first, and if reduction could be successfully performed, and access could be had to the rent in the diaphragm, it might not be necessary to open the chest.

General Plastic Surgery.—Dr. John Staige Davis, of Baltimore, stated that adequate practical training in the principles and practice of general surgery was necessary as a preparation for any real surgical specialty. This was particularly important for one who desired to specialize in plastic surgery, and consequently made its final teaching a postgraduate subject. The postgraduate student should have the opportunity of working in the outpatient department, the privilege of the operative clinic, with the expectation of assisting the operator and receiving personal instruction in operative technic, and eventually be allowed to operate under the eye of the chief. He should have the privilege of following the cases in the wards and of studying postoperative treatment, and the chance for clinical and experimental research on plastic problems. He should have the facilities to study the pathological material removed at operation. Men of special ability should be taken into the house on the plastic service and be given every opportunity to develop. The course should be at least one year, preferably two.

Mesenteric Thrombosis.—Dr. James F. Mitchell, of Washington, D. C., said that mesenteric thrombosis was of particular interest because of its gravity, the difficulty of diagnosis, and the poor results of surgical treatment. Pathologically the occlusion may be either venous or arterial, or both vessels might be involved. The patient under observation had no history of infection or trauma or any other condition which might explain the liberation of an embolus. The majority of cases which came into the hands of the surgeon were of this type, and this fact possibly offered a partial excuse for the extreme infrequency of a preoperative diag-

nosis. The superior mesenteric artery was occluded more frequently than the inferior, the usual explanation being that its diameter was nearly three times as great as that of the inferior; that it arose from the aorta at a higher point than the inferior; thus having an earlier opportunity of intercepting an embolus; and that its course was nearly parallel to that of the aorta, while the inferior ran off at an acute angle. The result of the occlusion was usually a hemorrhagic infarct, a pathological condition which had never been satisfactorily explained, except that while the superior mesenteric artery was not anatomically a terminal or end artery, it nevertheless was so physiologically. Operation at the earliest possible moment with immediate resection of the affected area, with a safe margin of healthy bowel, offered the best chance of recovery. The results were disappointing from a statistical point of view. The mortality in operated cases was variously estimated at from seventy-five to ninety per cent.

Accidental Ureteral Injuries During Pelvic Operations.—Dr. John M. Maury, of Memphis, Tenn., said that removal of the ligatures was the procedure of choice, and when done early there was good reason to expect a satisfactory result. It was more easily accomplished when undertaken before the organization of wound exudates had obscured the field. If for any reason there was delay, the least that one might expect was more or less complete stricture formation with incidental damage to the kidney and simple deligation would not suffice. In order of choice, ureterovesical implantation, ureteroureteral anastomosis or nephrostomy might be employed. In the event of the patient's condition precluding the possibility of choice, the least time consuming procedure must be followed and this was nephrostomy. Double nephrostomy might be done in a few minutes with the expectation that absorption of the ligature and canalization would result in due course of time, while the condition of the patient might make an anastomosis a formidable procedure. If canalization was not satisfactorily accomplished, the patient was in good condition for anastomosis or implantation. Severing the ureter and bringing the proximal end to the surface had been employed, but one could hardly imagine conditions under which one of the other methods would not serve a better purpose.

Spontaneous Hematoma Occurring in a Case of Spindle Cell Sarcoma of the Kidney.—Dr. Frank K. Boland, of Atlanta, Ga., said that the present case was spoken of as spontaneous hematoma instead of spontaneous rupture, because the hematoma, on account of its enormous size, was the outstanding picture rather than the comparatively small rupture. The case was unique for two reasons: First, because he had been unable to discover in the literature the report of a similar condition occurring in a neoplasm of the kidney; second, because the rupture of the kidney and formation of the hematoma were the first signs of the disease manifested in the case. Previous to this time the patient had been in good health, and presented no symptoms which would lead one to suspect her of having anything wrong with her kidney. Apparently the rupture occurred early in the course of the disease.

Significance of Pain in the Back.—Dr. Robert Carothers, of Cincinnati, stated that pain in the back was a reaction to irritation of nerves, caused either by direct pressure on the cord or its nerve trunks or indirectly reflected from elsewhere. The flat feet and buck knees were seldom without muscular and ligamentous strain in the back and pain which was relieved with proper treatment. Careful measurement of both legs in complaining patients would sometimes reveal that one leg was half an inch, perhaps an inch, longer than the other. A raised heel on the short leg usually proved the remedy to relieve a painful back in not a few subjects. In the listing spine, nerve trunks formerly pinched were now free. In diseases of the spine, pain was an incentive to study the case, and an early diagnosis which was so essential to success was not infrequently made, long before destruction occurred and treatment was given a chance to succeed.

Chronic Obstructive Jaundice.—Dr. William A. Downes, of New York, stated that all patients suffering from chronic obstructive jaundice should be operated upon, as surgery offered the only hope of relief. Internal drainage of the bile ducts was preferable to external drainage, in the same way that it was desirable, when possible, to anastomose around inoperable growths in the intestine to avoid the formation of an artificial anus. The slightly greater risk involved in anastomosing the gallbladder over simple drainage was more than offset by the increased comfort of the patient plus the added advantage of retaining the biliary secretion. Besides, in the event of a cure by external drainage, a secondary operation was necessary to close the fistula. Personally, he found it easier to unite the gallbladder to the stomach than to the duodenum, and since the passage of bile through the stomach was harmless, considered cholecystogastrostomy the operation of choice.

Typhoidal Osteomyelitis.—Dr. Nathan Winslow, of Baltimore, stated that persistent bone pain with a history of a previous typhoid fever should suggest the possibility of a typhoidal osteomyelitis. In suppurative bone disease a careful investigation of the bacteriology of the pus was necessary for an accurate diagnosis. When suppuration occurred surgery offered the patient the surest and quickest road to complete cure. Vaccinotherapy had been used with success in a few cases, both suppurative and nonsuppurative, with and without operation.

Fractured Spine.—Dr. Walter C. G. Kirchner, of St. Louis, said that in fractures of the spine too much stress had been laid on the diagnosis and treatment of the lesion itself, and not enough attention had been paid to matters relating to the welfare of the patient as a whole. As a basis for discussion he cited a case of pronounced fracture and dislocation of the fourth and fifth lumbar vertebræ in which there was complete paralysis of the lower limbs with loss of bladder and rectal function. In spite of high grade decubitus, emaciation and weakness, by careful handling and persistent attention to

detail, great improvement in the patient's condition resulted. The primary care of the patient must receive special attention. Treatment must be directed to the control of shock, the correction of deformity, relief of pressure on the cord, the prevention of sepsis, decubitus, and a state of inanition. The patient's mental state must receive attention. From the beginning, catheterization of the bladder should be avoided. Intelligent and painstaking nursing and mechanical measures were important factors in aiding improvement or recovery.

Papilloma and Adenoma of the Gallbladder.—Dr. Irvin Abell, of Louisville, Ky., stated that benign tumors of the gallbladder, notably papilloma and adenoma, were not so rare as formerly thought, occurring in the Mayo series once in every twenty-three and one half cases of cholecystectomy, and once in every thirty-six cases of the series he reported. The invariable presence of chronic inflammatory changes in gallbladders containing such tumors would argue the importance of chronic irritation as an etiological factor in their development. The overshadowing clinical picture was that of cholecystitis, there being no correlation of symptoms with the presence of such tumors. The fact that such tumors occurred in the course of chronic cholecystitis was an additional argument in favor of cholecystectomy.

The Influence of Hemorrhage on the Mortality in Gunshot Wounds and Other Injuries of the Abdomen.—Dr. James M. Mason, of Birmingham, Ala., said that the mortality of 88.8 per cent. in the large hemorrhage series, as compared with 31.5 per cent. in the small hemorrhage series, taught that our treatment of hemorrhage must be improved. Transfusion must be more extensively employed. Autoreinfusion should be practised in selected cases. If cases were seen early and observation indicated that hemorrhage was not progressive, operation might even be deferred a short time, while waiting for reaction, and while efforts were being made to obtain donors for transfusion.

Traumatic Brain Lesions.—Dr. E. Dunbar Newell, of Chattanooga, Tenn., said that a stereoscopic x ray picture should be taken of every head injury where the blow had been sufficient to cause a fracture of the skull or to render the patient unconscious. Fracture of the skull *per se* did not indicate that the patient had been seriously injured, with the symptoms of lesion of the brain or its membranes present, the absence of a fracture did not alter in the least the treatment nor the prognosis. The x ray not showing a fracture of the base did not mean that one did not exist. Basal fractures must not be considered hopeless cases.

Important Considerations in the Treatment of Fractures of the Shaft of the Femur.—Dr. Albert O. Singleton, of Galveston, Texas, stated that the early reduction of fractures of the femur under spinal anesthesia with the aid of the fluoroscope or x ray plates, and by placing the splint in position before reduction, would succeed in a number of instances in securing and maintaining good position. The Thomas splint was the splint of choice with provision for flexion of the knee. Extension was necessary in all cases, whether open or closed reduction, and whether or not plates or other methods of fixation of the bone were used. Skeletal extension or traction was superior to the skin when there was overriding of the fragments, particularly in fractures of the lower end of the femur. It was important not to neglect the muscles, tendons and joints and allow them to suffer from disuse and atrophy.

Chronic Ulcerative Colitis.—Dr. Harvey B. Stone, of Baltimore, said that patients with chronic ulcerative colitis presented a history of bowel trouble extending back for months and sometimes for a number of years. The onset might have been abrupt with acute dysentery or gradual and insidious. Often there were periods of improvement, sometimes of apparent cure, followed by recurrence and another cycle of improvement. The severe attacks were marked by numerous bowel movements—perhaps twenty or more a day—consisting largely of mucus, pus and blood. During these exacerbations there was loss of weight, abdominal pains, often severe, usually some fever, and marked weakness. Eating became difficult for these patients, not only because of complete loss of appetite, but even more because the entrance of anything into the stomach started immediate reflex peristalsis in the colon with sharp pain and urgent desire to defecate. Should the severe manifestations of the condition continue long, the patient became gravely ill, and it was not impossible for a fatal result to ensue. One of the striking clinical characteristics of chronic ulcerative colitis was its chronicity and recurrent nature. When it resisted medical treatment or became severe, operation was indicated. Ileostomy and separate appendicostomy for colon irrigations, with exclusion of the colon from function, offered the best results.

Patency of the Fallopian Tubes Ascertained by Transuterine Injection of Fluids.—Dr. I. S. Stone, of Washington, D. C., said that the method was first tried during the operation upon a young woman with acute bilateral salpingitis and appendicitis with extensive pelvic peritonitis. He was impelled to pursue a conservative course because the patient was expecting to be married in the near future. At that time it was considered folly to leave a tube which was dripping with pus, yet he allowed the left tube and corresponding ovary to remain *in situ*, although the specific nature of the infection was beyond question (the responsible party confessed it). After opening the abdomen and removing the right tube and ovary with the appendix, all of which were hopelessly destroyed, he proceeded with the injection. The cervix uteri was caught with a tenaculum forceps, a large glass syringe filled with hot mercuric bichloride, 1-1000, was introduced into it and passed through the internal os. Firm pressure with the hand caused a small stream of the solution to appear at the pavilion, which was caught upon a sponge and not allowed to flow into the abdomen. Besides the transuterine irrigation of the left tube, the same solution was used to irrigate its distal end by distention and flushing until he reached every possible fold in its mucosa. After a stormy first night the patient recovered, married, and bore her first child nine years afterward, and a second child two years after that.

(To be concluded.)

Abstracts from Current Literature

ENDOCRINOLOGY.

Normal and Morbid Conditions of the Adrenals with Special Reference to Dementia Precox.—Frederick W. Mott and Isabel Emslie Hutton (*British Medical Journal,* July 21, 1923) found the most constant change in the medulla of the adrenals in dementia precox to be an increased number of nuclei, irregularity of their size and form, and the deficiency of chromatin. There was, moreover, an increase of fibrous tissue which often took a pericellular arrangement and an increase of fibroblastic nuclei. In tuberculosis, there may be a great diminution of cytoplasm, but these nuclear changes are not seen. In general paralysis, the nuclear changes are not observed and the cytoplasm as a rule is not affected to any extent.

Function of the Parathyroids.—Harold A. Salvesen (*Journal of Biological Chemistry,* June, 1923) believes that calcium deficiency is the cause of the symptoms of parathyroidectomy, and that the theory of MacCallum and Voegtlin is probably correct. This is shown by the chemical findings of the blood in parathyroid insufficiency, experiments to determine the fate of calcium salts injected in tetanic dogs, and experiments on completely parathyroidectomized dogs preserved by calcium treatment. The conclusion is reached that the parathyroids control the calcium level of the blood, and by doing so, they influence the function not only of the muscle and nerve tissues, but probably of all the organs.

Importance of the Adrenal Glands in the Action of Certain Alkaloids.—Charles W. Edmunds and Putnam C. Lloyd (*Journal of Laboratory and Clinical Medicine,* June, 1923) conclude from experiments on dogs that the increase in the number of leucocytes and the change in the relative proportions which are produced in intact normal dogs by strychnine are due to the effect of the alkaloid upon the adrenal glands, that is, they are epinephrin effects. The number of red cells was not greatly altered as the amount of epinephrine produced is comparatively small, and to modify the number of erythrocytes, a large amount of epinephrin is required.

Goitre Problem.—As a result of the favorable impression created by his previous experience in the prophylaxis and treatment of goitre with sodium chloride added to definite amounts of potassium iodide, Otto Bayard (*Schweizerische medizinische Wochenschrift,* July 26 and August 2, 1923) administered iodized sodium chloride to the entire population of two villages, comprising 561 and 577 inhabitants, respectively. The amounts were 0.02 gram potassium iodide to five kilograms of cooking salt a year for each person. Soft goitres diminished distinctly and the younger the patient the more marked the recession. Goitres that were uninfluenced by this dose diminished in size by increase of the dose to 0.1 gram potassium iodide, without causing any unpleasant complications. For the purpose of a general prophylaxis of goitre in Switzerland, the author recommends a dose of 2.5 milligrams of potassium iodide to 5.0 kilograms of salt during the first year and an increase to 5.0, 7.5 and 10.0 milligrams in the succeeding years. He believes that more than half of the cases of cancer in Switzerland may be avoided by means of the prophylaxis of goitre, because the injuries resulting from hypothyroidism and the changes in the thyroid gland lead more readily to cancer.

Influence of the Thyroid Gland on the Response to Adrenalin.—D. Murray Lyon (*British Medical Journal,* June 9, 1923) states that in a comparison of the metabolic and cardiovascular responses to the injection of adrenalin in patients having similar basal metabolic rates, no relationship between the reactions is obvious. If individuals are examined on different occasions when their metabolic rates have altered, a change in the degree of response to adrenalin is noticed. Administrations of thyroid to a patient leads to an exaggeration of the reaction to adrenalin. In cases of exophthalmic goitre a fall in basal metabolic rate is not accompanied by a very great reduction in the sensitiveness to adrenalin, and it is suggested that this depends on a persisting hypertonus of the sympathetic system.

Anomalies of Carbohydrate Metabolism and Pancreatic Changes in Basedow's Disease.—In a study of 191 cases of Basedow's disease, Johan Holst (*Schweizerische medizinische Wochenschrift,* August 2, 1923) found diabetes in 2.1 per cent. of the cases, which must be assumed to be thyrogenic. He reports thirty-one cases, in which the carbohydrate tolerance was controlled and found not rarely that the diminution of the same ran parallel with the symptoms of Basedow's disease, and that patients who were favorably influenced by operation lost their glycosuria. In ten necropsies the pancreas showed changes and the number of islands of Langerhans were diminished. The author's results indicate that there is much to be said in favor of the theory that the products of the goitre, as a result of their incitatory effect upon the adrenalin, call forth mostly a functional, but occasionally, an anatomical affection of the pancreas. It may be assumed that this thyrogenic affection of the pancreas is the cause of the anomalies of the carbohydrate metabolism in Basedow's disease.

Involvement of the Nervous System in Malignant Disease of the Nasopharynx.—Henry W. Woltman (*Medical Clinics of North America,* July, 1923) states that malignant tumors of the nasopharynx are more common than is generally believed. The early symptoms are often entirely extranasopharyngeal and in fully one third of the cases lie in the field of the neurologist. In all cases of unexplained cranial nerve palsies, or in paralysis of groups of cranial nerves constituting well known syndromes, such as those of Jackson, of Avellis, of the jugular foramen, of the retroparotid space, and in cases of metastasis to distant parts of the body, the nasopharynx should be carefully examined by an expert. Pituitary tumor may be simulated, and all patients under examination for pituitary tumor should have an examination of the nasopharynx.

The resemblance of these cases to those due to primary involvement of the gasserian ganglion is often very close. A close cooperation between the rhinologist and the neurologist is most essential if ill advised operations are to be avoided.

Indications for the Surgical Treatment and Prophylaxis of Goitre.—B. Breitner (*Wiener klinische Wochenschrift,* March 22, 1923) asserts that merely the size of the goitre is rarely an absolute indication for operation, but that ptosis of the gland may be an indication. The transplantation of a substernal portion of the gland subcutaneously or subperitoneally may be required. Aside from the mechanical indication for surgical intervention (compression of the trachea or of the esophagus) as demonstrated röntgenologically, resection of a hyperthyrotoxic goitre should be done only in case of a diffuse colloid goitre without involvement of other endocrine glands. In the presence of a persistent thymus, pluriglandular insufficiency is probably also present and therefore an additional resection of the thymus is recommendable. In the presence of small, very vascular goitres, surgical intervention should be restricted and röntgenotherapy is preferable to the more difficult ligation of the thyroid arteries in these cases. The prophylactic treatment with iodine is favorably recommended.

Endemic Goitre in Lower Austria.—Johann Geringer (*Wiener klinische Wochenschrift,* March 8, 1923) comes to the conclusions that: 1. Goitre is a constitutional anomaly in certain regions, to which the female sex is particularly predisposed and which is usually transmitted with the parental germ plasm. 2. The absence or slight occurrence in the plains and its occurrence in the regions lying at a higher altitude speak in favor of an endemic disease, which is chiefly distributed in the higher altitude. 3. The cause of the occurrence seems to lie in a lack of ingestion of iodine. 4. Goitre often appears in the earliest youth, which fact justifies the assumption that the anomaly is transmitted even with the hereditary characteristics in these cases. 5. The assumption of an infection is not tenable. 6. Owing to the endemic nature, it is advisable to institute a course of iodine treatment with daily administrations of cooking salt, which course should be continued as long as the person who is affected with goitre or threatens to become so resides in the goitre region. 7. All goitre regions should receive only cooking salt having an iodine content of 0.004 per cent.

Thyroid Enlargement in Individuals without Sympathomimetic Manifestations.—Leo Kessel and Harold Thomas Hyman (*American Journal of the Medical Sciences,* March, 1923) say that the rôle of the thyroid in the production of clinical symptoms is greatly overemphasized. Of the fifty-five patients recorded in this paper forty-one had had attention specifically directed to the thyroid gland. Either the symptoms were attributed to a disturbance of the function of the gland, while the true pathological condition that was operative was overlooked, or else specific therapy was directed toward the thyroid without any relief of symptoms which could not possibly have been caused by thyroid disturbance.

Functions of Adrenal Glands and Their Relation to Concentration of Hydrogen Ions.—As a result of his observations, Robert McCarrison (*British Medical Journal,* January 20, 1923) concludes that the enlargement—with epinephrin content—of the adrenal glands in inanition and in avitaminosis may be correlated with the condition of acidosis associated with these states. Its occurrence, for the most part, during the terminal phases of avitaminosis, its association with marked respiratory disturbances, with oxygen want, with falling body temperature, and with interference with oxygenation, and its rapid disappearance on the provision of the missing vitamines, suggest that it is an emergency effort on the part of the adrenal glands. The attempted exercise of an emergency function by the adrenal glands may be expected to occur in all conditions of alkalosis or of acidosis.

Organotherapy in Neuroses and Psychoses.—Wagner-Jauregg (*Wiener klinsche Wochenschrift,* January 4, 1923) discusses chiefly the results of therapy with thyroid and sexual gland substances in the hebephrenic type of dementia precox, disturbances during puberty (infantilism, tics in young persons, etc.). In cases of excessive onanism the author achieved favorable results with bilateral ligations of the spermatic cord, both in regard to the somatic as well as the psychic symptoms. Thyroid treatment is recommended in every case of retarded development of children. In a combination of tumor of the pituitary with a goitre or symptoms of hypothyroidism, thyroid may improve the pituitary conditions and even the hemianopsia. It is well to remember in connection with hypofunction and hyperfunction of glands that qualitative changes (dysfunction) may be present. Thyroid and sexual gland substances produced complete recovery only in girls in whom the psychosis began at puberty and sex development had been arrested in the infantile stage. Good results were also obtained in nervous girls with hypoplastic uterus and much delayed menstruation.

Thymic Asthma.—Hugh Thursfield (*Archives of Pediatrics,* February, 1923) is inclined to believe that there is such a condition as thymic asthma, but that according to all evidence, clinical, pathological and röntgenological, it is exceedingly rare. The diagnosis is by no means easy; the most convincing syndrome is the coexistence of dyspnea with a protrusion of the manubrium sterni, abnormal dullness to percussion in this region, and a palpable and visible tumor during inspiration in the episternal notch. Thymectomy is rarely indicated; röntgen therapy is preferable. In the rare cases where the diagnosis is reasonably certain, and relief is urgently required, thymectomy is an operation with good results and a fairly low mortality.

X Ray Thyroid Therapy.—R. G. Allison (*Minnesota Medicine,* July, 1922) reports twenty-seven cases of Graves's disease without complications treated by x ray. Of these patients twenty-four are well, both from the clinical and laboratory standpoint, and the other three were operated upon with cure. No bad results or complications attributable to the treatments were seen.

Precocious Puberty.—Mark S. Reuben and G. Randolph Manning (*Archives of Pediatrics,* January, 1923) summarize the findings in their personal cases as follows: The röntgenograms of the pituitary were normal in all patients and all showed ossification of the wrist centres. Mentality was normal in six patients; one was backward and one was mentally deficient. Sexual desire was present in only one patient. Physical development was advanced beyond the age in five of eight cases studied. All but one patient had enlargement of the breasts; all had pubic and axillary hair; five menstruated and all showed enlargement of external genitals. In two patients there was concomitant enlargement of the thyroid; in one, carcinoma of the ovary; in one, enlargement of the ovary; in one, hyperplasia of the adrenals, and in one, tumor of the pineal.

DIABETES

Influence of Insulin upon Acidosis and Lipemia in Diabetes.—In view of the results obtained by H. Whitridge Davies, Charles G. Lambie, D. Murray Lyon, Jonathan Meakins and William Robson (*British Medical Journal,* May 19, 1923), it appears that insulin and carbohydrates, when given together in sufficient amounts to patients with diabetic acidosis verging upon coma, have a most beneficial and indeed spectacular effect. The rapid disappearance of the lipemia and ketone bodies of the blood, and the return to normal of the bicarbonate reserve, clearly indicate the means whereby this improvement is brought about. A great increase in the blood sugar may have no deleterious effect, in fact an adequate supply of carbohydrate is most important in the treatment of these cases, and in view of the known deficiency of glycogenic function, this supply must mainly be available in the form of sugar in the blood and tissues. If it is true that the acidosis in diabetes is the result of imperfect oxidation of fat through the inability of the cells to use carbohydrate, such results are quite to be expected.

It is noteworthy that the reduction of the blood sugar is not always accompanied by such an increase of the respiratory quotient as might be expected if the sugar had been burnt. The determination or respiratory metabolism in emotional subjects may not give a proper indication of the true respiratory quotient owing to irregularities of the breathing. Yet in such cases there is another factor to be considered. The liberation of alkali in the blood consequent upon the removal of the ketone bodies would result in a compensatory retention of carbon dioxide. This might easily be sufficient in amount not only to mask any rise but even to produce a fall in the respiratory quotient.

Physiology of Insulin.—H. H. Dale (*Lancet,* May 19, 1923) believes that insulin will prove to have an importance for physiology and medical science far beyond that of its use in the treatment of diabetes. There are doubtless cases in which the natural function has been so completely lost that not even a partial recovery can be anticipated. In such cases, insulin can prolong life and make it more tolerable, but only at the cost of daily injections which can never be remitted or reduced. Such a result is, in itself, worth attainment, but something much better ought to be aimed at. All the experience accumulated before the introduction of insulin pointed to the possibility of restoring to many diabetics a reasonable measure of normal function by giving their overworked remnant of islet tissue as complete a rest as possible. In many cases this was only achieved by a restriction of diet which was almost unbearable, though still compatible with life. If insulin is now used simply to enable such patients to eat a large quantity of food so long as they can tolerate daily injections, they will get no permanent benefit and insulin will be wasted. On the other hand, if it is used as an aid to the régime of dietary rest, to enable these patients to obtain some recovery of normal function without such cruel reduction of their diet; if it is used to bring into this class, for which some measure of restoration is possible, others in whom, without insulin, no diet sufficient for life would keep the blood sugar down and give the overstrained islets a chance of recovery; then, indeed, it will be used to the real advantage of the patients, and be worthy of all the extraordinary enthusiasm which its discovery has aroused.

Histological Study of Muscle Degeneration Produced by Local Injections of Insulin.—D. J. Bowie and W. L. Robinson (*Journal of Laboratory and Clinical Medicine,* June, 1923) studied tissues from rabbits which had received intramuscular injections of insulin, and also of saline, glucose, and adrenalin solutions for comparison. Such injections produced near their site a marked degeneration of the muscular fibres with leucocytic infiltration. Isotonic saline, however, produced only slight localized areas of degeneration, though the hypertonic solution had an effect similar to insulin. The authors believe that the lesions indicated by their studies following intramuscular injections probably explain the considerable pain and discomfort that is not uncommonly complained of and it may be pointed out that if the lesions can be produced by hypertonic saline, it is altogether likely that they might become quite extensive when various therapeutic agents are used.

Insulin in the Treatment of Diabetes.—Frederick M. Allen (*Southwestern Medicine,* September, 1923) reports the results in the treatment of two hundred and fifty cases of diabetes with insulin. It was aimed to give every child enough food to grow and develop normally, and every adult enough food to carry on his regular labor while remaining at least five or ten pounds below the normal standard for his height. The patients who can attain this ideal by diet are the ones who do not need insulin. The allowances of protein and carbohydrate are fairly liberal, perhaps one hundred gm. of each for a diet of two thousand calories. There is no sound basis for diets disproportionately and uncomfortably high in fat and low in carbohydrate and protein; acidosis is most safely avoided by avoiding such diets. The quantities of carbohydrate and protein allowed are ample, not merely for the prevention of acidosis, but for general health and comfort. The insulin requirement is kept within moderate bounds by moderate limitation of total calories and body weight. Never more than seventy units a day were used in the treatment of any uncomplicated case of diabetes and the average dose in the entire series was below twenty units a day. Apparently, as a result of the more thorough pancreatic rest afforded

by insulin, a few patients have shown gains of tolerance beyond what seemed possible by diet alone. No actual cure and no tendency to prolonged progressive improvement have been observed. On the other hand, no downward progress, indicated by a need for reduced diet or increased doses of insulin, has occurred in any cases under thorough treatment. In conclusion, Allen states that it is feasible for patients at their homes to remain free from glycosuria and nearly free from hyperglycemia under combined treatment with diet and insulin. Overnutrition makes freedom from glycosuria difficult and exposes to acidosis, infection and other dangers. Insulin revolutionizes the results of diabetic treatment, but cannot atone for lax dietary methods.

Studies of Diabetes Mellitus.—William S. McCann, R. Roger Hannon, and Katherine Dodd (*Bulletin of the Johns Hopkins Hospital,* July, 1923) discuss the effects of iletin administered to ten children. One of the ten patients was entirely uninfluenced by it in the dose used, but the other nine derived some benefit from the treatment, measured objectively in terms of blood sugar values, decreased glycosuria, and in control of ketosis, as well as in the relief of symptoms. In most cases two injections daily were required. A wide variation in individual susceptibility to the effect of insulin was seen when the same lots of extract were compared in different patients. Complicating infections played an important rôle in this difference. When given subcutaneously, it has been the custom to use the amount which will render the urine sugar free for from twelve to thirteen hours with the patient on a bare maintenance diet. The patient is instructed to keep always at hand a small amount of carbohydrate to use in case of need. Orange juice is recommended, but cane sugar is much more convenient. Adrenalin to counteract an overdose of insulin is not recommended, because it is not reliable. The extra calories which patients were enabled to utilize to the unit of insulin varied from twelve to seventy calories, and the amount of extra carbohydrate which was utilized per unit varied from 0.5 to 3.6 gm.

Interrelationship of Blood Fat to Blood Sugar.—The work of T. H. Oliver and A. Haworth (*Lancet,* July 21, 1923) indicates that the blood sugar has a relation to the blood fat, other than that of a mere oxidizing agent. Fat properly absorbed into the tissues seems to increase the storage of carbohydrate; if not absorbed, or if mobilized by calcium, the storage is interfered with. Possibly improper storage of the fat may account for the tendency of a high fat diet to produce glycosuria in some cases of diabetes. Practically all conditions which lead to a hyperglycemia lead to lipemia as well; this may be attributed to a diminished oxidation. It has been possible to produce a distinct rise of blood fat in addition to a hyperglycemia by the injection of adrenalin (from 0.48 to 0.56 per cent.); in this case, at least, it is difficult to understand why the liberation of a large amount of oxidizing material should be accompanied by an increase of the substance to be oxidized. A more probable explanation is that both were stored and liberated together, an explanation which recent work on the effect of insulin in diminishing lipemia does much to confirm.

Hyperglycemia.—Henry M. Feinblatt (*Journal of Laboratory and Clinical Medicine,* May, 1923) found in the course of two thousand routine blood sugar determinations that eighty one patients yielded blood sugar readings in excess of 150 mg. to the 100 c.c. In forty two per cent. of the patients who showed hyperglycemia, clinical diabetes mellitus was demonstrated. In the other group of apparently nondiabetic patients, the presence of the abnormally high blood sugar could only be explained in a small percentage of cases. The author does not believe that a single report of an unusually high blood sugar can be considered pathological, since a transient hyperglycemia may result from emotional disturbances. A study of the cases emphasized the inconstancy of the relation between glycosuria and hyperglycemia.

Nature of Blood Sugar.—L. B. Winter and W. Smith (*British Medical Journal,* May 26, 1923) conclude as follows: 1. There is definite evidence that a reactive sugar is present in the blood. 2. There is no chemical evidence that glucose is formed in the body. 3. There is definite evidence that some of the blood sugar of diabetics is fundamentally different from that or normal persons. 4. No evidence at present exists that the intestine plays an essential part in the causation of this difference.

An Investigation of the Picramic Acid Methods for Blood Sugar.—Henry C. Sweany and Ethel M. Johnson (*Journal of Laboratory and Clinical Medicine,* May, 1923) used the more recent method of Benedict, and the Myers and Bailey modification as the most representative of the picramic acid methods, and for comparison, that of Folin and Wu. In addition to the determination of blood sugar, a definite quantity of sugar was added to each blood filtrate and the amount recovered was estimated. The copper reduction methods and the picramic acid methods showed serious discrepancies in certain pathological subjects. The presence of phenol or potassium phenyl sulphate in blood produced a false sugar result with the picramic acid methods. The results of this work indicate that the modified method of Folin and Wu has many advantages over any of the other methods studied. The authors suggest that the picramic acid methods may be used to determine the presence in the blood of "reducing substances other than glucose."

Report of a Case of Diabetes Treated with Insulin.—In a detailed study of a moderately severe case of diabetes, by E. I. Spriggs, D. V. Pickering and A. J. Leigh (*British Medical Journal,* July 14, 1923), in which tolerance had been diminishing for the last three years, it was found that with the help of two daily hypodermic injections of insulin, on a measured diet, the excess of sugar in the blood, the sugar in the urine, and the acidosis could be controlled; also that the patient could take more than double the amount of food he had previously been able to take without the appearance of sugar in the urine. Regulation of diet is still needed, for if an excess food was taken above the new and higher level of tolerance, the hyperglycemia, glycosuria, and acidosis reappeared. The treatment led to improvement in the nutrition, physical capacity, mental outlook, and appearance of the patient.

Medicolegal Notes.

WORKMEN'S COMPENSATION.

A claimant under the New York workmen's compensation act, who had received the amount of an award thereunder for injuries sustained by falling from a piazza roof, sued the physician who treated him for malpractice. The New York Supreme Court, Special Term, Warren County, sustains the defendant's contention that the plaintiff's remedy under the workmen's compensation act, having been accepted, is exclusive, and bars an action against the physician. "There can be but one recovery for the same wrong. Satisfaction by one joint tort feasor has always been considered a bar to an action against another. . . . The workmen's compensation law does not alter this just and salutary principle." The employer having responded in full for the injury, including the malpractice claimed, if any action lay against the physician, it was held to be one in favor of the employer, who had been subrogated to such right.

HYPOTHETICAL QUESTIONS ON CROSS EXAMINATION.

The Indiana Supreme Court holds McHargue v. State, 139 N. E. 316, that hypothetical questions on cross-examination of an expert witness should be limited to taking his opinion upon matters of which there is some evidence, at least, except as the trial court, in its discretion, may permit questioning to test the knowledge and skill of the witness.

But within the facts of which there is any evidence at all when an expert witness has expressed his opinion based on facts assumed by the part introducing him to have been established by proof or upon a hypothetical case put by such party, the other party may cross examine him by taking his opinion based upon any other set of facts assumed to have been proved by the evidence, or upon a hypothetical case put by the cross examiner.

X RAY PLATES IN EVIDENCE.

A physician, who was a specialist in the use of the x ray, called as a witness by the plaintiff in an action for personal injuries resulting from being run over by an automobile truck, testified respecting certain x ray pictures purporting to be of the plaintiff's pelvic region (where the principal injury claimed by her existed), which were explained by the witness in response to questions by counsel for defendant. The witness testified that the x ray plates showed an abnormal condition of the pelvis, particularly with reference to the relation of the bones, some of which were alleged to have been fractured. The witness produced another x ray plate, which he testified showed the pelvic bones of a normal person. This plate was admitted. Its admission was the subject of an exception by the defendant.

The Massachusetts Supreme Judicial Court holds, McGrath v. Fass, 139 N. E. 303, that, since it is well settled that an x ray plate showing the physical condition of a plaintiff in an action for personal injuries is admissible, there is no valid reason why a plate of another person properly verified by proof which showed the pelvis in its normal condition, was not competent to assist the jury in understanding the nature and extent of the plaintiff's injury, in the same way that a skeleton is often exhibited in similar cases. Whether the plate was sufficiently verified was a question of fact for the trial judge.

HYPOTHETICAL QUESTIONS AS TO CAUSE OF DEATH.

On a trial for murder, a doctor was asked, on cross-examination, the hypothetical question whether, if a man was found lying beside the roadside with two black eyes, one entirely and the other almost closed, and bruises on his nose and the back of his right hand and bruise marks on his elbow, and between his hand and his elbow, and if he had been lying there fourteen hours and then died, and if, when his skull was taken off, a large blood clot was found covering the left hemisphere of the brain and having a maximum thickness of three quarters of an inch, and entirely between the dura mater and the pia mater, and if it all slid off without adhering to anything, whether he thought there was any chance of the clot having been due to apoplexy. He answered that it would not be apoplexy. The Massachusetts Supreme Judicial Court holds, Commonwealth v. Williams, 139 N. E. 347, that the hypothetical question was properly admitted.

But a question on direct examination to a witness for the defendant, who testified that he had heard the medical evidence introduced by the state, and, from the evidence he had heard, had formed an opinion as to the cause of death, "What in your opinion caused the death of Decker?" was held rightly excluded, for the reason that the facts upon which he was expected to base his opinion were not stated, and medical and other evidence were conflicting.

WORKMEN'S COMPENSATION ACT FOR MEDICAL SERVICES.

The Louisiana Supreme Court holds, Delaney v. Ferd. Brenner Lumber Co., 97 So. 349, that an employer, or his insurer, who makes payments for medical, surgical and hospital service in excess of the amount provided therefor by the workmen's compensation act must obtain the employee's express consent in order to be entitled to reimbursement.

CONSTRUCTION OF MISSISSIPPI PRIVILEGE STATUTE.

In an action for personal injuries it appeared that the plaintiff was treated by one physician, and examined but not treated by another. The latter at plaintiff's instance testified as to his injuries. The defendant on objection by the plaintiff was not permitted to prove by the other physician what his examination and treatment of the plaintiff disclosed. The Mississippi Supreme Court holds, Brookhaven Lumber & Mfg. Co. v. Adams, 97 So. 484, that under Section 3695, Mississippi Code 1906 (Hemingway's Code, Section 6380), a physician is incompetent to testify to facts which come to his knowledge by virtue of his being employed by his patient as a physician, without the consent of the patient; and the patient does not waive the privilege because he introduces another physician who testifies for the patient about the same facts.

INDICTMENT HELD NOT TO STATE OFFENSE UNDER HARRISON ACT.

The Circuit Court of Appeals, Fourth Circuit, holds, Pendleton v. United States, 290 Fed. 388, that an indictment alleging that while the accused was a practising physician and a person required to register under the Harrison Anti-narcotic Act, he had in his possession 2.31 grains of morphine, although he had never registered, charged no offense. "It did not," the court said, "attempt to set up any violation of sections 1006 et seq. of the Revenue Act of February 24, 1919, 40 Stat. 1130. It was obviously drawn under the original Antinarcotic Act (38 Stat. 785) which the Supreme Court years ago held did not penalize the mere possession of narcotics. U. S. v. Jin Fuey Moy 241, U. S. 394. The court gains no added strength from the allegation that the defendant was a practicing physician. As such, he was not required to register unless he dispensed narcotics. There is nothing in the record to show that he did."

Synergistic Anesthesia and Analgesia in Surgery

By JAMES T. GWATHMEY, M.D.,
Anesthetist to People's Hospital,
and GEORGE SCHWARTZ, M.D.,
Adjunct Surgeon to People's Hospital and Instructor in Operative Surgery, Post-Graduate Medical School and Hospital,
New York.

The term synergistic anesthesia means the reciprocal augmentation of the action of one or more drugs upon one another with unconsciousness. Synergistic analgesia is the term employed when consciousness is present.

ADVANTAGES.

Magnesium sulphate, nitrous oxide and oxygen, and morphine have each proved dangerous and unsatisfactory when used alone and to the point of saturation. To avoid the dangers of nitrous oxide and oxygen when used alone, and to secure the relaxation demanded by the surgeon, in the vast majority of administrations a little ether is necessary for complete relaxation. Exactly what is meant by just a little ether may be determined by the size of the ether container attached to any apparatus, varying from a four ounce container to a quart measure. Nitrous oxide oxygen is uneven in results and is unsatisfactory in about fifty per cent. of cases, even to dentists. Charles K. Teter, of Cleveland, one of the pioneers of modern gas oxygen anesthesia for general surgery, as well as dentistry, uses a small amount of warmed ether with every dental patient. M. Ecker, a dental specialist of New York, after an experience with over fifty-five thousand cases, now uses synergistic methods, passing the nitrous oxide oxygen over a fifty per cent. mixture of anesthol and paraldehyde. He has at present over fifteen thousand synergistic cases to compare. His opinion is therefore valuable.

He states that each patient receives in addition to the nitrous oxide and oxygen only a few drops of the mixture, but the result is a safer and deeper anesthesia, free from cyanosis and excitation, with no movement or flinching during the operation rendering holding straps unnecessary for the heretofore fifty per cent. of unsatisfactory cases. With the synergists the patient is pink from start to finish, recovery is smoother, with less after hysteria than with the straight nitrous oxide and oxygen. As a sequence to the increased safety, ease and comfort of operating upon an unflinching patient, the physical and nervous strain upon the operator under the old system is entirely removed, and this conservation of energy is a factor that should not be ignored.

Until this time, the only way to avoid ether for general surgical cases and obtain a satisfactory nitrous oxide oxygen anesthesia was by using nitrous oxide oxygen asphyxial anesthesia, or some preliminary medication, usually morphine. By administering the hypodermic tablet in a solution of magnesium sulphate instead of plain water, we can usually eliminate the unpleasant aftereffects that sometimes follow morphine when given in sterile water, in addition obtaining a much longer analgesic effect.

Magnesium sulphate used alone is not a satisfactory anesthetic for human beings. Morphine scopolamine anesthesia, according to Wood (1), in 1906, had a mortality of one death in 221 administrations. But Thorek (2), in 1921, states that this method is safe. On the other hand, a study of half a million administrations in the United States shows conclusively that sequences and combinations immediately increase the value of all anesthetics as regards life. Neither nitrous oxide and oxygen, nor magnesium sulphate, nor morphine are deleterious to the tissues of the human body, nor do any of them have an affinity for any special organ. Meltzer's laboratory experiments with magnesium sulphate over a period of thirteen years would seem to prove this. It has also been proved clinically by the analysis of the liver of a patient who had received four hundred c.c. of a four per cent. solution of magnesium sulphate by hypodermoclysis, and who died on the operating table from hemorrhage after the right auricle was accidentally wounded. There was found to be 13.8 milligrams of magnesium to the 100 grams of dried liver, or as the liver is seventy-five per cent. water, 3.45 milligrams to the 100 grams of non-desiccated liver, i. e., about normal.

The statement by a recent writer that magnesium sulphate has a special affinity for the liver is evidently based upon an inaccurate analysis. Rector (3) made the magnesium blood determinations on five

Copyright, 1924, by A. R. Elliott Publishing Company.

patients according to the method of Kremer and Tisdal, at hourly intervals for a period of four hours. It was found that the magnesium reached its maximum concentration in the blood within one hour after its administration and thence gradually diminished returning to normal at the end of four to five hours. In the five cases the normal magnesium content of the blood was found to average between three and four milligrams to the 100 c.c. of serum. (Chart I.) The three agents, morphine, magnesium sulphate and nitrous oxide and oxygen, used synergistically, produce analgesia with unconsciousness and give full relaxation of the muscles with a greater margin of safety than the usual deep third stage anesthesia with nitrous oxide oxygen alone. The relaxation by these synergists is comparable to spinal analgesia, which gives a more complete brain block than any inhalation method heretofore used, but avoids the dangers of this latter method.

Two avenues of administration are available, one by hypodermoclysis beneath one or both breasts and the other by sigmoid instillation. Formally we give thirty c.c. of chemically pure twenty-five per cent. solution of magnesium sulphate under one breast besides the quarter grain morphine that the patient was given by hypodermic injection. We soon discontinued the administration of the magnesium sulphate by hypodermoclysis because it was rapidly absorbed and so enhanced the action of the morphine that we had had several cases of morphine poisoning from one quarter of a grain of morphine. At the present time we are using the sigmoid instillation method exclusively. The night before operation the patient is given a cleansing soapsuds enema, and this is repeated at seven the following morning. At 7:30 the patient is given by rectum two hundred c.c. of a four per cent. solution of magnesium sulphate with four drams of paraldehyde, and which is allowed to remain in the sigmoid. At the same time the patient is given one eighth of a grain of morphine by hypodermic injection which is repeated in twenty minutes and a third injection given twenty minutes later which makes three eighths grain of morphine which the patient has received. By 8:30 the patient is drowsy and can be taken to the operating room. For vaginal work no inhalation anesthetic is necessary, as a rule, but if the abdomen is open a few inhalations of nixtrous oxide oxygen is required to make the skin invision, division of fascia and peritoneum. The inhalation may then be omitted for the entire operation, again it may be necessary to use it intermittently during part of the time occupied by operative procedure. Occasionally when much traction of the viscera is necessary a little ether may have to be added to the nitrous oxid oxygen.

FURTHER ADVANTAGES.

1. The sedative action is prolonged to such an extent that morphine postoperatively is rarely needed.
2. There is little paresis of the intestines and less acidosis; nausea and vomiting are practically eliminated, except when the gallbladder has been emptied or removed.
3. The amount of ether is lessened, thus reducing to a minimum bronchial and renal irritation and also causing less acidosis.
4. No deleterious results follow the use of synergists.
5. There is no distention and no gas pain.
6. The preoperative emotional factors do not appear, as the patient is convinced that the disagreeable effects and aftereffects of the inhalation anesthetic will not occur. The fear, dread and anxiety of the operation room is not present, as the patient does not know when he is to be taken from his bed. The exhaustive effect of surgical trauma is almost completely abolished, an analgesia begins one hour

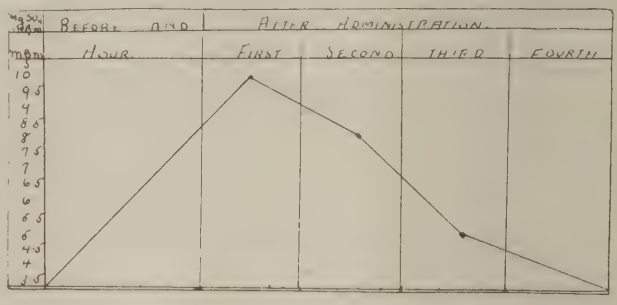

CHART I.—Showing the magnesium concentration in the blood (Rector) with rapid elimination and return to normal after four hours.

previous to operation measure, and continues for half an hour to one hour following the return to bed.

Vomitus is seldom seen following return to consciousness, when cracked ice is given with no ill effects. The return to bed is followed by quiet, restful sleep, interrupted only by individual desires, or obedience to instructions. The changes in pulse, respiration and blood pressure, in their respective phases, are most constant in proportional difference.

The most conspicuous result in using synergistic analgesia, with and without inhalation anesthesia, is the total absence of shock or exhaustion. In a wide range in abdominal, pelvic and plastic surgery there has been no untoward incident chargeable to the synergistic combinations.

CONCLUSIONS.

When properly given and safeguarded, certain things are common to the two methods outlined.

1. The patient's condition, when brought to the operating room, varies from a seemingly normal condition to unconsciousness. The conscious patient may answer questions intelligently, immediately before and after operation, but when placed in bed will rest quietly for several hours. Upon awakening he remembers little or nothing of the operation, and in fact some patients do not know they have been operated upon until told.
2. Nausea, vomiting, wound and gas pain are more nearly eliminated by synergistic methods than by any third stage inhalation method, even the best.
3. When supplemented by nitrous oxide oxygen or by ether given to unconsciousness, or by local analgesia, the patient is not cyanosed at any time, neither is the alkali reserve even temporarily lowered. These two factors may account for the absence of nausea and vomiting in so many cases.

A Contribution to the Etiology of Asthma*

By M. A. RAMIREZ, M.D.,
and A. V. ST. GEORGE, M.D.,
New York.

During the course of activities on the problems of protein sensitization, it was found that a not inconsiderable number of cases after extremely careful examination did not fall into one of the groups of pollen, epidermal, food, dust or bacterial sensitizations. However, an outstanding feature in these patients in the anamnesis was a strikingly similar history of digestive disturbance—irregular diarrheas, periodical constipation, nausea, headaches, vomiting, etc.—and in addition, asthmatic or urticarial symptoms, or both. After careful clinical and laboratory examinations two prominent features were generally encountered. One, an indicanuria; the other protein putrefaction in the freshly voided stool (acid stool and excess of gram negative organisms with few or no gram positive organisms. The indicanuria at times was only faint and in a few cases absent, the putrefaction being invariably present.

Upon the basis of these findings, the possibility of some protein cleavage product or products, developing during digestion and inducing a susceptibility, suggested itself. During intestinal activity, histamine as one of the cleavage products of protein hydrolysis, and as a probable precursor of those aromatic bodies which appear in the urine and feces, looms as important.

Histamine is an amine and was discovered in 1907 by Windhaus and Vogt, who prepared it synthetically from aminazolylpropionic acid. Subsequently it was isolated by different workers from ergot, soya sauce and soya beans. In 1910, Ackermann obtained it from pure histidine hydrochloride by the action of putrefactive bacteria. Mellanby and Twort next described a method for the isolation of a bacillus of the colon group from the contents of the intestine of man and other animals which is capable of converting histidine into histamine. With certain similar researches carried on at about the same time by various investigators, the conclusion soon gained ground that histamine formation in the intestine was the result of bacterial activity. Abel and Kubota, however, although accepting the possibility of histamine formation from bacterial activity, "found a histamine like substance in so many proteins of both animal and vegetable origin, that the bacterial formation of the base may well be considered negligible." Abel and his coworkers, in some brilliant researches, showed among other findings that the active principle of pituitary extract appeared to be histamine. They also isolated it from Witte's peptone and from various tissues, secretions, etc., of lower animals. Their theories and conclusions, while perhaps not acceptable to all in their entirety, are nevertheless well worth serious perusal and careful consideration. Among their findings one statement may be mentioned as applicable to the problem under consideration. Man takes into his digestive tract a certain amount of preformed histamine with each meal, but as the result of digestion, experimentally shown by Abel and Kubota, an additional quantity of this base is formed. Some interesting conceptions and theories are also given concerning the necessity of this substance (histamine) in the physiological economy of the organism, which, however, it is not necessary to enter into here.

Histamine as a probable factor in the causation of traumatic shock has been considered by various investigators, and the work of Dale and Laidlaw, Dale and McIntosh, Bayliss, Cannon, a number of French army surgeons, and latterly Abel, must be consulted, as the subject is beyond the province of this paper. Toxic effects from the amine have also been produced by Dale and Laidlaw, Olhume, and others.

Lastly, the possibility of histamine as a factor in the production of anaphylaxis has been suggested. It is the rôle histamine plays in this condition that forms the subject of this paper.

With these observations in mind, an attempt was made to study a group of patients along certain lines. This group, for lack of a better name, was called tentatively endogenous asthma, or allergy. Solutions of chemically pure histamine obtained from Kahlbaum were made in various strengths, 1-500 to 1-100000 dilutions. These solutions were used in testing out the groups of patients by the scratch method. It was finally found that a dilution of 1-10000 was the best strength to employ for testing purposes. The details of this method are familiar to all, hence the conclusions only are given. All persons react to histamine in some degree when the latter is introduced into the skin. The reaction, however, is two to three times more intense—speed; extent; wheals (fifteen to thirty mm. in diameter), intensity of the reaction—in individuals who manifest symptoms of endogenous asthma, than in those who apparently do not suffer from histamine sensitivity.[1]

Chemical analyses of the blood were made according to the methods of Folin. Routine stool analyses carried out according to the methods of Schmidt, Herter, and others, for the determination of putrefaction, fermentation, etc., and the bacterial examination of the intestinal flora. The twelve cases tabulated in the chart are illustrative of the type of cases, the principal symptoms and the result of examinations.

The principal points in the history may be summarized as follows: Patients with socalled endogenous asthma do not as a rule react to the various proteins tested, but give an exceptionally strong reaction with solutions of histamine (1-10000). Practically every person tested with histamine gives

*From the Laboratory and Department of Immunology, French Hospital, New York.

[1]Koessler in his studies on histamine, etc., carried out similar tests, but did not apply them for purposes of diagnosis.

[2] 1. B.M. indicates basal metabolism before treatment and 2. B.M., basal metabolism after treatment.

a wheal, but in cases of endogenous asthma patients give exceptionally large wheals (fifteen to thirty mm. in diameter). We have recorded the results of this test on our chart with one to four plus—one plus representing a wheal fifteen mm. in diameter, two plus twenty mm. in diameter, three plus twenty-five mm. in diameter, and any over twenty-five mm. as four plus. The patients frequently present such symptoms as poor appetite, moderate anemia, lassitude, malaise, and frequent headaches. Recurrent attacks of urticaria are common. Bowel evacuations are extremely irregular, usually quite sluggish. The blood pressure readings are usually low and these patients all seem to present an associated disturbance in the physiology of their glands of internal secretion.

The chemical examination of the blood shows nothing distinctive, except possibly an increased chloride content. The stool examination results usually in an acid stool with considerable albumin putrefaction with or without an associated carbohydrate fermentation. We generally find an excess of gram negative organisms.

The following brief outline of treatment was followed: Ten cases were treated with hypodermic injections of histamine, beginning with one minim of a solution containing a half mg. to the c.c. and gradually increasing this dose up to six minims of a solution containing two mg. to the c.c. We were unable to give any larger doses than this without immediately causing severe headache, flushing of face, weakness, urticarial rash, etc. Two of the patients were markedly improved while on the small doses, but became worse when the dose was increased. These patients subsequently made a complete recovery under peptone treatment, receiving injections twice a week for three months and no other treatment. They have been free from asthma for several months and a year, respectively, and skin tests with histamine show a markedly diminished reaction. The remaining patients were favorably influenced by peptone injections. Keeping the intestinal tract free from stasis is obviously necessary. Colonic irrigations and measures tending to a simplification of the intestinal flora are also indicated.

The author's references will appear in his reprints.

The 1923 Epidemic of Grippe*

By B. M. RANDOLPH, M.D.,
Washington, D. C.,
Professor of Clinical Medicine, Medical Department of George Washington University.

This subject is chosen for the purpose of bringing to the surface, through discussion, a clinical picture that is fresh in our minds. It is my hope that the observations noted herein will be so checked and amplified that we shall have formulated through this meeting a completely rounded conception of the epidemic of respiratory inflammation that has prevailed here and elsewhere during the winter just past.

It is important to begin by trying to decide what it is that we have been dealing with. To me it appears that it is not different from what occurs regularly every winter with greater or less frequency and severity. Just what is the primary etiological factor has not as yet been determined beyond question. I am strongly of the opinion that it is not identical with the pandemic that visited us during the late summer and autumn of 1918, and persisted throughout the ensuing winter, though I do believe that many of the cases called flu that winter were not cases of the specific epidemic, but were identical with what occurs every year.

Those of us who remember the epidemic of grippe of 1890-91 will recall that it was the common belief throughout the years which followed that those who had grippe were predisposed to recurrent attacks; that clinical types multiplied, the literature of that decade abounding with reports of intestinal grippe, grippe arthritis, grippe cardiopathies, grippe neurasthenia, etc.; and that at the same time observers began to lose the earlier impression of the intense infectivity of the disease, some asserting that it was very slightly or not at all communicable. And so the term grippe passed into the medical language of that generation as applying to almost any acute infection of the upper respiratory tract, and to a number of other disorders, losing entirely the meaning it had when it was originally introduced with the original epidemic.

This history seems to be repeating itself in the case of flu, which is the popular designation of the epidemic of 1918. I feel that it is exceedingly important that the question of identity should be answered correctly. I am unable to accept the opinion of certain authorities that the great epidemics which recur quite regularly once every generation are the result of an accidental concentration of factors, which convert an annual disease into an overwhelming epidemic. The eighteenth century speculation as to what might be the intensifying agent was that it was "some inexplicable disturbance in the bowels of the earth." The most recent is that it is due to the fact that our solar system is at the time passing through some particularly insalubrious area in space. We may take our choice.

If the clinical appearances, as seen in the individual patient, did not furnish sufficient data upon which to base the differentiation, epidemiological observation would supply the deficiency:

1. The manner of spread. In July, 1918, influenza appeared in the Charlestown Navy Yard, and spread thence over the country, radiating, as though by infiltration, or along routes of travel, as by metastasis, while our seasonal epidemics of grippe break out in a multitude of widely separated localities simultaneously.

2. The pandemics of 1890 and 1918 possessed an intensity of infective power, unequalled by anything except measles, a phenomenon certainly not possessed by the grippe of the present epidemic.

MORBIDITY AND MORTALITY.

The epidemic of 1923 began in Washington early in January, and, at the beginning, was characterized by a very high morbidity, but by a mild course. Most patients were well in a few days, and some did not even have fever. Toward the end of January there was a marked subsidence in the morbidity wave, this ebb being followed in February by another wave. The number of cases in this second wave was not so great as in the first, but there was a much higher percentage of serious cases, and a very decided mortality increase. Histories now showed a large percentage of patients who had not fully recovered from an initial attack, that is, relapses. Even in those who had not been ill previously the malady seemed to be more virulent the later it occurred.

CLINICAL PICTURE.

The most frequent mode of onset was what appeared to be a cold in the head, slight sore throat, or mild tracheal irritation. This lasted one to several days. Then developed an abrupt seizure with headache, a congested sensation in the paranasal structures, burning sensation in the eyes in some cases, generalized muscular pain, marked surface hyperesthesia, chilly sensations, sometimes general, sometimes confined to the back, loss of appetite, constipation, fever 100° to 102°, a sense of dryness, tightness, pain, or oppression along the tracheobronchial tract. The pulse varied, in some cases being less than one would expect with the degree of fever present, in others being very rapid. The respiratory rate was rarely increased, and in many cases was lower than normal. I have seen a number of cases in which the rate was twelve to fourteen a minute. This is a very valuable point in the differential diagnosis from pneumonia. There is irritating cough, and often sneezing and other evidence of irritation of the nasal passages. In the early stage there is little or no exudate. Later there is a mucopurulent discharge, the cough becomes productive, and there is at the same time a decrease in the discomfort suffered.

Physical signs in the chest consist of coarse intensified breathing heard in the paravertebral spaces at the level of the inferior angles of the scapulæ, and often extending upward over the upper lobes. Where a frank bronchitis develops, large and small bronchial râles may be present over the entire chest. Often there is a localized bronchitis.

*Read before the Medical Society of the District of Columbia, Washington, D. C., March 28, 1923.

COURSE

It appears that the progress of the disease may be arrested anywhere in the respiratory tract. The primary attack may be aborted, or the infection may extend throughout the respiratory tract, culminating in diffuse or disseminated pneumonia. Extension may be continuous or intermittent, slow or fulminating; the duration is therefore exceedingly variable. It is, in my experience, very characteristic for resolution to be associated with one or more profuse sweats. This is often alarming to patients, and they are much comforted by the assurance that it marks the beginning of recovery. Convalescence is slow, and associated with physical and mental depression, which may be profound and protracted. This depression lasts a few days in the mild cases, and often ends quite abruptly. In others, in whom the disease has run a more severe or prolonged course, or who were asthenic to start with, it may last many weeks. This stage requires careful study to prevent imprudence, and may be very trying to both patient and physician. Sometimes the physical signs of congestion about the lung hilum persist for some time after the patient is apparently well.

In this epidemic I have in five cases observed a phenomenon that I have never noted before, nor have I seen it described in the literature. In frank bronchitis, in the second stage, where the dry stage has given place to the exudative and before resolution has begun, there have appeared the physical signs of a typical bronchial asthma, as seen between paroxysms, i. e., mixed moist râles everywhere heard, high pitched whistling inspiration, prolonged noisy expiration. This condition lasted two to four days, and completely disappeared. None of the patients were habitual asthmatics. All were over forty; two were over fifty. One gave a history of having had an asthmatic convalescence following a severe bronchitis eight years before, but never at any other time. Two had recovered from pulmonary tuberculosis, one three years ago, and the other within a year. Several colleagues have told me that they have met with similar cases.

Patients with chronic infection of the tonsils or accessory nasal sinuses are almost sure to have an exacerbation during or following an attack of this disease. Indeed, an attack of grippe is often the starting point at which a focal infection begins to show troublesome activity. I have now under observation a patient who has furnished an opportunity of seeing the beginning of the infectious process.

Case.—P. M., a child of five, had been a perfectly healthy specimen since birth, her only malady having been an attack of chickenpox in her fourth year. In January, 1923, she contracted the prevailing grippe, apparently in school. It took the common form of a febrile bronchitis, which lasted three days, so that she was out of school only a week. In the meanwhile her elder sister contracted acute tonsillitis, to which she had been subject. About ten days after the initial grippe the patient (P. M.) manifested abruptly fever and loss of appetite. Examination showed the tonsils moderately inflamed with a crypt exudate characteristic of follicular tonsillitis. The condition was so mild that no treatment was prescribed other than bed and a liquid diet. Next day she had two convulsions in rapid succession. Under bowel cleansing and alkaline treatment by mouth, there was no recurrence of constitutional symptoms. The urine showed a well marked reaction for diacetic acid. The upper anterior cervical glands (those draining the tonsils) were now found to be enlarged, indurated and tender. The fever soon subsided, and the involvement of the glands diminished. For the following two weeks she got along well when at rest, but whenever she exerted herself at play, and once when she got excited, there was a recurrence of fever. Then, without warning she had a sharp transient pain in her ear. Examination showed a bulging drum, which was immediately incised, and discharged turbid serum. In two days there was established a profuse discharge of pus, containing hemolytic streptococci in pure cultures. Later there was a recurrence of bronchitis; finally suppurative mastoiditis.

The point of interest in this case in connection with the present discussion is whether this child's tonsils were infected at the same time and by the same organism that caused the primary attack of grippe, or whether she contracted tonsillitis from her sister. It is to be noted that she had had repeated opportunities before to contract her sister's infection, of which she had not availed herself.

I wish to impress the point that the terms grippe, influenza, flu, and the like have absolutely no meaning in the scientific sense. Until an etiological differentiation can be established, we shall have to rely on clinical data for our guidance. The researches of Olitzky and Gates, of the Rockefeller Institute, may ultimately furnish the solution of the problem, but the proof cannot be conclusive until they are tested by a genuine pandemic, such as that of 1918, and for that we shall probably have to wait many years. These investigators cultivated from the nasal secretions of three patients of the 1918 epidemic, and from one patient in 1920 (the patients being examined in the first hours after the onset of their disease), a filterable organism, which they have termed the Bacterium pneumosintes. The following is their summary (1):

"Cultivation of Bacterium pneumosintes in the collodion sac dialysate of a tissue medium produces an antigen suitable for serological tests."

"Injection of dialysate cultures of Bacterium pneumosintes into rabbits results in the production of antibodies demonstrated by agglutination, precipitation, complement fixation and phagocyte reactions."

"Four strains of Bacterium pneumosintes, three from the first epidemic influenzal wave (1918-1919), and one from the second (1920), show identical antigenic characters."

"The blood serum of rabbits experimentally injected with glycerolated active material of rabbit passages contains specific agglutinins for Bacterium pneumosintes, whereas, normal rabbit serum does not."

The organism is an obligate anerobe, and subcultures are preserved from the original strains, but show a diminished pathogenicity for rabbits. The observers have not been able to recover Bacterium pneumosintes since, from more recent cases, but this is not conclusive, as laboratory accidents have interfered with continuous experimentation. It may be

that the next six months will furnish information on material secured by them from the present epidemic.

It is to be hoped that these researches will result in the discovery of the essential cause of such pandemic scourges as that of 1890 and 1918. But history warns us against too hasty acceptance of this organism as the specific cause. It will be remembered that in 1892 Pfeiffer discovered the bacillus of influenza that bears his name; that this bacillus was accepted as the cause of epidemic influenza for twenty years; that doubts then began to arise as to whether this organism was the real cause; and that since the 1918 epidemic there are hardly any competent observers who have not rejected it.

All the evidence that I have been able to procure points to our old enemy, the streptococcus, as the responsible factor in such epidemics as the recent one. I presented a paper before this society in 1916 (2) advancing this view, and I have, as yet, met with nothing to cause me to change that opinion. Of course the mere occurrence of streptococci in the exudates from the respiratory lesions is not sufficient evidence, but when we uniformly recover these organisms in pure culture from the complicating lesions, the empyemas, the meningitides, the septicemias, the bone abscesses, we have something to go upon.

The objection usually raised to this hypothesis is that streptococci are found everywhere, and if they are so virulent, we should all have died long ago. But it is not scientific to consider a thing impossible because we cannot explain it. There is nothing required for the acceptance of this hypothesis that does not find analogy in the accepted facts of bacteriology.

It is known that more than eighty per cent. of our population is sooner or later infected with tubercle bacilli, and yet a relatively very small percentage ever have clinical tuberculosis.

It is known that diphtheria and typhoid originate from healthy carriers.

It is known that strains of streptococci which are nonvirulent for animals may be made virulent by cultivation on such animal's blood serum, or whole blood.

It is known that streptococci increase in virulence for a susceptible animal by passage through such animal.

It is known that immunity to infection is relative, and differs with different organisms. An attack of smallpox confers an immunity that is practically absolute and permanent. The immunity conferred by infection with the tubercle bacillus, on the other hand, rapidly fades in susceptible individuals, and requires a recrudescence of the disease to be restored.

It is accepted that streptococci may rest latent in a body focus for a long time without producing symptoms either local or general; and that general symptoms may arise from such infection without local, and *vice versa*.

Taking these accepted facts into consideration, along with the immense number of streptococcus open surface carriers known to exist, it puts no strain on the reason to regard this organism as the primary infecting agent in such a disease as that described above, and that grippe is primarily an autoinfection.

On the basis of this hypothesis and of previous observation, I was able in January to prophesy what took place, viz., that there would be a recession of the January wave of mild type, this to be followed by a recrudescence which would be characterized by a more serious pathology and a higher mortality. My explanation of this is as follows:

Those patients who had the disease in January, who did not completely recover and had a more severe attack later, were victims of autoreinfection, their own strain having become more virulent through its recent pathological activity.

Those cases in which the patients were ill for the first time in the epidemic and who suffered more severely than those in the early cases were the result of contagion. It is to be remembered that autoinfection does not exclude contact infection, and that in so far as the cases were the result of contagion, those infected late would be expected to meet with more virulent organisms than would the earlier contact cases.

The clinical picture of our recent epidemic corresponds with the pathological anatomy of streptococcus infection. Streptococci possess in a very high degree the faculty of spreading along lymphatic structures. Surgeons have learned to dread this organism, on account of this virulent tendency in their cases of cellulitis, tenosynovitis, parametritis, and similar conditions. In the respiratory tract the development of the inflammation corresponds exactly to the anatomy of the lymphatics. We recall that all the efferent lymphatics of the head, oral cavity, nasopharynx and tonsils, after passing to the cervical lymph nodes, are collected into the deep jugular trunks, which empty on the right into the angle of the vena cava, and on the left into the thoracic duct. The submucous lymph plexuses of the trachea are drained by vessels which pass through the tracheal walls, and, joining with their fellows, empty into the tracheal and hilus lymph nodes. Similarly, the lymphatics of the bronchial subdivisions and lungs drain ultimately into the mediastinal lymph nodes. There is free anastomosis of the lymph plexuses underlying the mucous membranes of the nose and its sinuses, of the nasopharynx, larynx, trachea and bronchi, that is, lymphatic communication from the nose to the mediastinal glands and lungs. Clinically, when our patient gets an infectious inflammation of the upper air passages, if his immunizing reaction does not inhibit its spread, there is an extension downward of the inflammation in a fashion exactly analogous to that seen in erysipelas; and the manner of extension is the same, i. e., by infiltration of the infecting agent through the subepithelial lymph spaces.

PROGNOSIS.

The prognosis depends on the virulence of the organism for the affected individual, on the promptness with which the patient establishes immunity, and on the completeness of the immunity established.

TREATMENT.

While nothing is offered in the way of treatment that is of a specific character, I am sure that wise management, coupled with cooperation on the part of the patient, does much to shorten the attack, to lessen its severity, and to prevent complications and relapse. The most important essential is rest in bed, that is, complete confinement to bed from the *onset*. This

should be maintained, not merely till the fever reaches normal (it often falls to subnormal in the morning one to three days before the evening rise disappears), but till there has been a continuous absence of fever for forty-eight hours. Sufficient time should be given for convalescence, and this period should be watched to prevent fatigue or other indiscretion. This is the best protection against complications and relapse. At the onset the indications are for catharsis, diaphoresis and anodyne effect. In my experience these are met by the old combination of calomel, Dover's powder, and acetphenetidin, as well as by any other. The second day I invariably begin the administration of moderate doses of an alkali, generally sodium citrate, and keep it up through the febrile period in uncomplicated cases. Regulation of the bowels and control of the cough are usually the only other indications for drugs. During convalescence we may find that tonics for the heart, nervous system, or appetite are indicated. It is important that residual local infection, especially of the nasal sinuses and throat, should receive expert attention.

And in spite of all we can do, the surgeons will for the remainder of the year reap their harvest from the seed sown during the first two months.

Glandular Fever and Influenza

By SAMUEL STALBERG, M.D.,
Cleveland, Ohio.

In the autumn of 1919 I observed an epidemic of six cases of glandular fever in a rural community of northwestern Pennsylvania. Two months after the subsidence of the last case this territory was visited by the influenza epidemic which swept the country for the second time since 1918. The cases were not studied as carefully as might be desirable, especially from the laboratory viewpoint; but sufficient clinical observation was made to fairly establish the diagnosis.

My reasons for reporting these cases are: 1. The disease occurs rather irregularly, occasionally goes unrecognized, and even its place in the nosology is still disputed in some quarters. 2. Pestis minor and other forms of benign lymphadenitis are frequently seen either before or after epidemics of plague. In view of this fact and of the resemblance of glandular fever, at least in the nature of its local lesion, to pestis minor, the occurrence of this small epidemic, preceding the severe outbreak of influenza, is pointed out, for whatever significance that may attach to it.

A brief survey of the rather interesting history of this disease and of its clinical picture is in place. A more complete account of the same may be found in the list of references.

HISTORY.

E. Pfeiffer (1) in 1889 was the first to call attention to the disease as a clinical entity, under the name of *drüsenfieber.* However, Protassow (2) asserted that it had been described by Filatow, of Moscow, in his clinical lectures somewhat earlier. Dawson Williams in 1897 was the first in England to recognize the condition and his paper (3) was followed by communications from several practitioners who had observed cases answering the description of the disease without having diagnosed it. In this country recognition of the condition antedated that of England. J. Park West (4) in 1896 reported to the New York Academy of Medicine the largest epidemic ever recorded, consisting of ninety-six cases observed in a rural district in eastern Ohio. The epidemic, however, was spread over a period of three years. In March, 1897, Samuel McC. Hamill (5) reported one case to the Philadelphia Pediatric Society, and presented an excellent review of the subject "in the hope that interest might be stimulated in a subject which seems to have been especially neglected in this country." Roussel read a paper on the same topic before the Philadelphia County Medical Society in the same year. Reports of small epidemics and of sporadic cases were fairly frequent thereafter. Since 1914, however, no reference to glandular fever can be found in the literature until July, 1920, when Rosenblüth, of New York, reported six cases "observed in the past two years." In 1921 Tidy and Morley (6), in England, reported two cases and gave a fine résumé of the subject. Morse, in this country, also reported two cases the same year. In both of these papers a detailed blood picture is given. It is noteworthy that this is virtually the first time that attention has been paid to this important phase of the disease. Recently Sprunt and Evans (10) reported a series of six cases of adenitis with interesting blood changes, to which they give the name of infectious mononucleosis. Under the designation acute benign lymphoblastosis Bloedorn and Haughton (10) of the United States Naval Hospital at Annapolis, report a series of four cases with an almost identical picture. Morse (9) is of the opinion that all these are undoubted cases of glandular fever, but because unrecognized were given new names under the impression that they were new diseases. Parenthetically, the memory of the profession is peculiarly poor in the matter of diseases which appear at irregular or infrequent intervals. On its reappearance the condition is often hailed as a new disease. An illustration is afforded by influenza. Each new pandemic, arriving two or three decades after the previous one, astonishes and shocks by the rapidity of its spread, its high morbidity, and considerable mortality. Several instances prove the same to be true in glandular fever. Rudolph (11) in 1914 points to articles and

letters in the *British Medical Journal* describing what the authors deemed a new disease but which was in his opinion glandular fever. Tidy (12), in 1921, discussed a communication to the *London Times* by a medical correspondent describing a mysterious infection which was also in all probability glandular fever.

SYMPTOMATOLOGY.

Definition.—Glandular fever is an acute infectious disease of unknown bacteriology, occurring in small epidemics, principally in children, and characterized by fever and swelling of the deep cervical lymph nodes.

After an incubation of about seven days the child is taken ill with fever, nausea, occasionally vomiting, and heavily coated tongue. There is tenderness and stiffness of one side of the neck, usually constipation and frequently abdominal pain. On the second or third day a swelling is seen, usually on the left side of the neck, due to inflammation of the deep cervical glands beneath and anterior to the sternomastoid muscle at about the middle of its length. The glands are tender to the touch and often attain considerable size. There is no tonsillitis or pharyngitis. There may be some infection of the pharyngeal mucous membrane, but not sufficient to account for the degree of adenitis. The swelling remains stationary for two or three days, and then begins to subside slowly. In most cases the glands on the other side of the neck begin to enlarge at about the time that the swelling on the original side has reached its maximum, and runs a similar, though usually a less severe, course. Occasionally the adenitis is unilateral; and infrequently it appears first on the right side. Suppuration practically never occurs. Many cases show enlargement of the axillary and inguinal glands. These, however, never attain the size of the cervical swellings. The mesenteric glands are often palpable. The parotid and submaxillary glands are not affected. The liver and spleen are enlarged in a considerable number of cases. Epistaxis has been seen by a few observers. Rarely, a transient rash is present. The fever and acute symptoms begin to subside after the fifth or sixth day, but the glandular swellings may not completely disappear before the end of three weeks. Convalescence in the more severe cases is slow and attended with marked debility and anemia. Complications are few; nephritis, which is occasionally hemorrhagic, being the most common one. Otitis media has been seen a few times. Prognosis is good, there being practically no mortality.

Hematology.—As stated before, it is only within the past year or two that any attention has been paid to blood examinations in glandular fever. Much light may be expected on the nature of the disease by similar work in the future. The essential change is a leucocytosis of 17,000 to 20,000 due mainly to the increase of the lymphocytes to from seventy-five to eighty-five per cent., many of the cells being of the Riedel or bilobar type. These were the findings in Morse's and Tidy and Morley's cases. The return of the blood count to normal was gradual, corresponding in time to the decrease in size of the glands, liver, and spleen.

A similar blood picture obtained in the cases of Sprunt and Evans and Bloedorn and Haughton. In both of the last mentioned reports the conclusion is drawn that the leucocytosis is the result of reaction to an infection which causes first a slight damage to the blood forming organs, followed by stimulation of the lymphoid elements. These cases were not called glandular fever by the authors, but Morse considers them undoubted instances of that disease. A perusal of the case histories certainly shows a close resemblance to glandular fever; the points of difference being the somewhat greater pharyngeal involvement, the larger number of glands affected, and the age of the patients, all of whom were young adults. In this connection it may be mentioned that Tidy and Morley (7) quote Breinil, Priestly and Fielding, who described an endemic of glandular fever which occurred in North Queensland, Australia, which was known as Mossman River fever, and of which many hundreds of cases were seen since 1877. It attacked mostly adults, and the axillary and inguinal glands were the ones affected. At the end of the first week, a leucocytosis of 12,000 to 15,000 with forty-five per cent. of lymphocytes developed. These cases are clearly not glandular fever.

The normal lymphocytosis of children is not quite as high as that seen in glandular fever.

ETIOLOGY AND PATHOLOGY.

Etiology.—Glandular fever is primarily a disease of childhood. Pfeiffer gives the age as "under fourteen." In Park West's series the ages ranged between seven months and thirteen years. A young mother of affected children is occasionally attacked, and a few epidemics among adults have been reported. Botchkofsky's (13) fifty-four cases observed among soldiers in the Russian Army is the largest of these. The sexes are equally susceptible.

Epidemicity.—Pfeiffer stated that the disease occurred in small epidemics, especially house epidemics. Park West's ninety-six cases occurred in forty-three families, about twenty children in these families escaping. Fisher records eight cases in one family and Chapman five cases in his own family (11). The evidence points to the disease being mildly contagious.

Bacteriology.—No specific organism has been discovered. Streptococci, staphylococci, pneumococci, and Bacillus influenza have been found in cultures from the mouth and pharynx and the blood.

Pathology.—No histological studies of the glands have been made. In the only case in which a necropsy was made, reported by Korsakoff (13), the glands showed hyperplasia of the parenchyma with inflammatory changes. Most of the glands and the spleen were enlarged, and the kidneys were the seat of glomerulonephritis. Streptococci were present in the pus from the cervical glands, which had suppurated before death, and were isolated from the axillary glands, the liver, spleen, kidneys, bone marrow, and heart's blood.

NOSOLOGY AND DIAGNOSIS.

Nosology.—The majority of the writers on the subject agree that glandular fever is a disease *sui generis*. This view is based on the fact that the condition possesses all the elements of an acute general infection with local manifestations, viz., its occurrence in epidemic form, its sudden onset, the definite and selflimited course; the involvement, in

addition to the glands, of the liver and spleen; and the nephritis. Nor can the source of the infection be placed in the pharynx, as might be supposed from the fact that the deep set of cervical glands that are characteristically affected in glandular fever drain the lymphatics from the tongue and pharynx. The small amount of pharyngeal catarrh even when present, and the involvement of the mesenteric glands, liver and spleen, point to a different origin.

Some observers do not recognize glandular fever as a distinct clinical entity. Holt does not mention it in the latest edition of his textbook on *Disease of Infancy and Childhood*. Griffith (14) in 1900 reported several cases which followed closely the picture of glandular fever. However, because other members of those families were suffering from influenza at about the same time, he was inclined to consider them merely a "lymphatic manifestation of grippe"; admitting that if influenza had not been active he would have unhesitatingly called them glandular fever. This view is not tenable, because glandular enlargement is rare in influenza. At any rate Griffith is hardly justified to draw from this incident the general conclusion that "it even throws doubt upon the reality of the disease." In his recent textbook (15) Griffith has not changed his views in the matter. Hand (16), while admitting that the symptom complex was well established, considered that the clinical evidence shows variations in the etiology in different cases; and that the condition often, but not always, is one of the protean manifestations of influenza. Some French writers also refuse glandular fever a place in the nosology. Gallois, quoted by Tidy, regards it as only a special form of influenza.

Differential diagnosis.—With the clinical pictures of glandular fever in mind it should not be hard to distinguish it from secondary adenitis and the tuberculous and syphilitic forms. From those cases of mumps in which the submaxillary glands alone are affected it is differentiated by the enlargement of the deep cervical glands, liver and spleen, its other features, and, probably, the blood count. In West's ninety-six cases, fifty-seven patients gave a history of having had mumps previously or had it subsequently. In Case I of my series bilateral mumps developed one month after complete recovery from the glandular fever. Parenthetically, I utilized this occurrence as proof to the parents that the previous condition had not been mumps. Like the majority of the laity they considered all swellings in the vicinity of the lower jaw mumps. As to glandular fever, they had never heard of it. During the prevalence of the glandular fever in the village there was one other severe case of mumps with complicating orchitis, in a boy of sixteen who lived about a mile distant.

The blood findings in glandular fever bear a striking resemblance to those in acute lymphatic leucemia. This, together with the glandular enlargement common to both conditions, will often make the diagnosis difficult for a short period. However, the milder course, the early remission of the active symptoms, the lack of signs of hemorrhage, and the relatively lower leucocyte count will serve to distinguish glandular fever. It is well to bear in mind in this connection the normal lymphocytosis of children.

GLANDULAR FEVER AND INFLUENZA.

The question naturally suggests itself as to whether there is any significance in this occurrence in my experience of the epidemic of glandular fever and influenza within two months of each other. A brief discussion, necessarily academic, may probably be pardoned, with a view of establishing any possible connection between the two conditions. The opinion of some authors as to the identity of the two diseases has been referred to under nosology. The comparison may be made under three headings:

1. *Epidemiological.*—Glandular fever occurs in small, usually house, epidemics; at times sporadically. Influenza comes in pandemics, epidemics and sporadically. With regard to the concurrence of the two diseases in epidemics, not many instances are found in literature. It may be pointed out that Pfeiffer's article on glandular fever was published in 1889, when the great influenza pandemic of 1889-90 began. Griffith's cases of probable glandular fever occurred during the prevalence of influenza. Rosenblüth's six cases were observed in the years 1918, 1919 and 1920. Dick, in March, 1921, reports in the *British Medical Journal* a case of glandular fever in a child and comments that "the theory that the infection may be a type of influenza may have something in it, for shortly after his illness a very widespread outbreak beginning among school children developed here." Several other communications in the same volume of the journal report cases of glandular fever. My own series occurred in 1919. It is also noteworthy that a revival of interest in glandular fever is seen during the past few years.

2. *Pathological* and *symptomatological.*—In glandular fever the deep cervical glands and occasionally other glands in the body are the seat of inflammation. In influenza there is little or no glandular involvement, but there is more or less intense inflammation of the mucous membrane of the upper respiratory tract and pharynx, with frequent bronchopneumonic complications. In glandular fever there is little or no respiratory or pharyngeal involvement. In glandular fever the liver and spleen are frequently enlarged; in influenza, infrequently. In glandular fever there is lymphocytosis; in influenza, leucopenia.

Incubation period in glandular fever is about seven days; in influenza, a few hours to a few days. In glandular fever there is constipation. In influenza, constipation or diarrhea, more frequently the latter. In glandular fever there is frequently nephritis; in influenza, occasionally congestion of the kidney. Both are acute general diseases, with fever and its accompaniments.

3. *Etiological.*—Glandular fever attacks children mainly; influenza all ages, principally during the third and fourth decades of life. A specific organism has not yet been discovered in glandular fever. Neither has the causal relation of Pfeiffer's bacillus to influenza been conclusively established. This comparison would seem to indicate that there must be but little resemblance in the nature of the two diseases. The only basis for any association between them lies in the undetermined etiology which is common to both.

Other diseases are supposed to travel in the wake of influenza epidemics. As examples are cited the prevalence during and after the late influenza epi-

demic of encephalitis lethargica and cerebrospinal meningitis. The same thing obtained in the epidemic of 1889-90. Finkler (17) refers to the reports of "a new disease called sleeping sickness," which had broken out in some parts of Italy in 1890; and to several cases of encephalitis reported in Germany by Leichtenstern in the same year. The association of these diseases with influenza is explained by Hamer (18) on the theory that one and the same infecting agency operates in all of them. Howell (19) offers in explanation the possibility that a variety of microorganisms can, under certain conditions, give rise to encephalitis, and in support of this view cites the occurrence of the latter condition in connection with poliomyelitis and influenza. It may be noted that this view is identical with the one advanced by Hand in the case of glandular fever.

GLANDULAR FEVER AND PESTIS MAJOR AND MINOR.

Pestis minor is now known to be, bacteriologically, a variety of plague, during epidemics of which it is often seen. The plague epidemic which is at present prevalent in many parts of the world, and which has appeared in New Orleans and other parts of the United States, began in 1894, supposedly in China. James Cantlie (20) who had observed five thousand cases, in a lecture before the Epidemiological Society of England in 1896, soon after the epidemic started, relates several instances of the occurrence of pestis minor during plague epidemics and discusses at length the epidemiological significance thereof. He also refers to other allied adenopathies observed by himself and others. His observations and conclusions are not without interest in connection with glandular fever. "Time and again," he says, "has it happened that before an outbreak of plague, during a period varying from a few months to several years, buboes with fever have been observed in a more or less epidemic form." The following are some of the instances mentioned: In 1877 a variety of plague infected Astrakan which was classed as pestis minor, from which none died and but few were confined to bed. The following year an outbreak of typical plague occurred 150 miles higher up on the Volga. In Calcutta, in 1890, four years before the outbreak of plague, fever with glandular swellings existed among the British troops. In the Far East, at Singapore and along the coast of China as far as Shanghai, from 1892 to 1896, singular affections of the inguinal glands were prevalent, "which occupied the attention of the Singapore and Hong Kong branches of the British Medical Society." Dr. E. D. Dickson, physician to the British Embassy at Constantinople, writing of the outbreak of plague in 1876-77, is quoted, "Two or three months previous to the manifestation of plague in Mesopotamia glandular swellings free from fever prevailed in this country. They showed themselves in the groin, armpits, and neck. . . . They began to appear about the end of autumn and continued through the winter, but towards the end of it the plague broke out and reached its acme of intensity in the spring. . . . On the cessation of the plague apyretic glandular swellings reappeared precisely similar to those which had preceded the outbreak and they continued to manifest themselves about two months longer." A form of glandular enlargement which is of particular interest, because it resembles glandular fever, is referred to by Cantlie by recalling that in 1891 he had reported twenty-three cases to the Hong Kong Medical Society of an affection consisting of the enlargement of one gland, seldom more, in the necks of children, over the sternomastoid muscle at its anterior border. The disease appeared infectious, was attended by feverishness, and there was no throat affection. Cases also occurred after the date of that report. The parotid and submaxillary glands were not involved, but the practitioners, for the want of a better name, called the condition mumps. Williams (3) comments on this report of adenitis among children as follows: "Whether the Hong Kong cases are more nearly allied to glandular fever or to pestis minor it would be useless to speculate, but the observation is interesting and may turn out to be of much epidemiological importance." That pestis minor was observed in previous epidemics of plague is shown by reference to Sydenham, who wrote of the Great Plague of London, 1864-65, "At times tumours may break out without fever or important symptoms. . . . Those to whom this happens may walk about in public as usual." Fedore observes, in 1820, "In the Levant and in the Marseilles epidemics of 1820 cases were to be seen which were not ushered in by any alarming symptoms, in which the natural functions were not disturbed, and in which buboes appeared without fever or with only slight fever. It is the benign plague of authors which is observed when the disease commences and when it is at an end, though it is rarely seen in the middle period, which is entirely devastating, *but it is not less plague.*"

This was written, remember, over sixty years before the plague bacillus was discovered by Kitasato and Yerson. Cantlie draws the following conclusions: "That long periods of time may intervene between the prevalence of specific glandular swelling (pestis minor) and the outbreak of malignant plague, and that the former may continue for years after the major form has disappeared, that independent outbreaks of glandular swellings may come and go and no plague supervene; and that the bacillus in pestis minor, at first of a low toxic power, attains malignancy by passing through the intermediate host possibly, but not probably, the rat." The rôle of neither the rat nor the flea in the transmission of plague had as yet been discovered.

Clinically, glandular fever and both forms of plague, but especially pestis minor, possess many points in common. In both diseases lymphadenitis is the local lesion; the site, however, being reversed. In glandular fever the glands affected in nearly all cases are the cervical; in plague the inguinal glands are attacked in seventy per cent. of the cases, the axillary in twenty per cent., and the cervical and maxillary in five to ten per cent. Multiple buboes are more common in plague. Suppuration of the buboes is common in plague; rare in glandular fever. The spleen and liver are involved in both conditions. Incubation period is about the same in both, three to seven days. Leucocytosis is present in both. But while glandular fever resembles pestis minor in the relative mildness of the course and very favorable prognosis, it lacks the picture of pestis major produced by the general intensity of its symptoms. There is absence of the more severe forms of cerebral

and nervous disturbance; of great prostration; of sloughing of the skin over the buboes and of the petechiæ caused by capillary hemorrhage; and of the seventy per cent. mortality. The point of distinction is, of course, bacteriological. In plague the Bacillus pestis is readily found in the glandular tissue and blood smears, and, postmortem, in the viscera; in glandular fever the causative organism has not been determined.

OTHER ADENOPATHIES.

Climatic bubo.—Among the varieties of glandular enlargement mentioned by Cantlie in his lecture on plague is one which was first described in a paper by Naval Surgeon G. C. Godding, in which he refers to many cases of chronic glandular swelling, usually inguinal, which occurred in epidemic form on board ship and among soldiers on shore, and which was a source of perplexity to the medical officers of the Army and Navy. This condition is now known as climatic bubo. Inguinal buboes develop which have no relation to venereal infection. Rost (21) thinks that the disease is contracted by sexual intercourse with prostitutes of the colored races and that it is much more common in the West Indies than elsewhere. It does not affect the male natives, and never affects children. The affected glands are only slightly tender, and no other glands in the body are involved. The fever is of an irregular, remittent type. "The incubation period is about five weeks, the course is protracted and a secondary anemia often develops. It is differentiated from plague by the mild course, as patients seldom seem sick; by the absence of very painful buboes and extreme illness"—Stitt (21). The germ has not been discovered.

Recently Sala (22), in Italy, reported that in his region the wave of influenza and epidemic encephalitis was followed by a local epidemic of nine hundred cases of jaundice. This in turn was followed in August, 1921, by an epidemic of twenty cases of inguinal buboes. These sometimes ulcerated, and at first suggested bubonic plague. All of the patients recovered after three or four months. A micrococcus was isolated from the glandular lesion.

Among infections which show glandular swelling may be mentioned trypanosomiasis, caused by a protozoan. The glands affected are those of the posterior cervical triangle.

INFLUENZA AND PLAGUE.

When the 1918 influenza epidemic, with its surprising intensity, invaded the country, many people declared it to be "the plague." Of course, this point need not be argued, because plague is readily determined by the presence of the specific bacillus. As MacCallum (23) observes, "It would have been impossible to miss the plague bacillus in cultures from the very first case." But there is some resemblance between the clinical course of the more severe cases of influenza and that of plague, especially the pneumonic form. A brief comparison of the two conditions may be included in the scope of this paper.

Epidemiology.—Both influenza and plague occur in pandemics and epidemics. The latter, however, is slower and more limited in its spread, never extending in one epidemic over the entire earth, as does influenza. Both also occur in smaller, more limited epidemics.

Etiology.—Plague is caused by the Bacillus pestis. In influenza the specific cause has not yet been definitely established. The voluminous bacteriological work since the recent influenza epidemic points to the conclusion that Pfeiffer's bacillus, while frequently the predominant organism in that disease, is not the only germ standing in causal relation; nor, in some cases, does it play even a leading part. As MacCallum (23) states, "The influenza bacillus is a common and important pathogenic invader of the lung, but strictly a secondary bacteriological invader, responsible for the pneumonia it may be, but not proved to be the cause of the primary epidemic disease." Norris and Landis (24) think that the influenza bacillus opens the door to various other organisms which are often the cause of the complications. The mode of transmission is the same in influenza as in the pneumonic form of plague, viz.: droplet infection; but, of course, totally different from that of the bubonic form.

Pathological.—Hemorrhagic processes are more or less common to both diseases. The type of pneumonia observed in the 1918 epidemic of influenza was a confluent bronchopneumonia and at times an interstitial form. A copious, bloody exudate was present in the bronchioles and lung tissue and the color of the pneumonic areas was blackish red, red, or grayish red (24). Areas of the consolidated lung were often necrotic. The bronchi, trachea, larynx and pharynx were the seat of intense inflammatory changes. The invading organisms, whether Bacillus influenza, pneumonia bacillus or streptococcus, were usually numerous, frequently loading the phagocytes lying free in the exudate and packing the alveoli and bronchi (23). In primary pneumonic plague "the pneumonic process is at first lobular, later involving the entire lobe. Microscopically, there is a destruction of the alveolar and bronchial passages with a hemorrhage exudate. There is marked congestion of the bronchial mucosa. Plague bacilli pack the exudate in the bronchi and bronchioles" (Stitt) (21). In influenza, meningitis or encephalitis was noted only in a few of the more severe cases, while in plague (bubonic form) congestion of the meninges and extravasation into the brain substance is common. But the organs characteristically involved in bubonic plague, the lymphatic glands, spleen and liver, are seldom affected in influenza.

Clinical.—Marked physical exhaustion, cyanosis, dyspnea and stupor are common features in influenzal pneumonia and in both the pneumonic and bubonic varieties of plague. Bloody sputum is present in influenza and pneumonic plague. There is leucopenia in influenza, leucocytosis in plague. Cardiac failure occurs in both influenza and plague, more frequently in the latter. In both influenzal pneumonia and primary pneumonic plague the physical signs in the lungs are disproportionately meagre compared with the pulmonary symptoms. Norris and Landis (24), in speaking of the hemorrhagic form of influenzal bronchopneumonia, remark: "The condition is not unlike that seen in the pneumonic form of plague." Stitt (21) states, "An influenza pneumonia may show the general prostration and cardiac weakness of plague."

COMMENT.

One is not justified in drawing any definite conclusions from the data given above. Pestis major and

minor are caused by the same bacillus. The latter occurs at certain periods with relation to epidemics of the former. Whether the few recorded instances of the occurrence of glandular fever before or during influenza epidemics has the same significance, cannot be said. Glandular fever and influenza do not resemble each other clinically to any marked degree, but both are of unknown etiology. Whether glandular fever occupies the same position as other infections of unknown etiology that are occasionally seen in connection with influenza epidemics, cannot in the present state of our knowledge be stated.

REPORT OF CASES.

CASE I.—C. B., male, aged four years. None of the diseases of childhood previously. First seen on October 17, 1919, on the second day of his illness. There was pain, stiffness and tenderness on the left side of the neck, heavily coated tongue, temperature 102° F. and rapid pulse. Throat was clear. On the following day the temperature was higher, and there was headache, general distress and some abdominal pain. There was a considerable glandular swelling at about the middle of the neck under the sternomastoid muscle, which was tender to touch. The pharynx was slightly congested. The patient was constipated. The illness increased in severity during the following few days and he was occasionally delirious. The swelling increased in size, attaining the maximum on the 21st of October, remained stationary for about five days, and then began slowly to subside. It was tender and hard to touch. On October 24th the glands on the right side of the neck at about the same site as on the left were enlarged, but the swelling was neither as large nor as tender as that on the left side. The temperature varied between 102° and 104°, fell slowly and reached normal on about October 27th. On October 21st considerable stomatitis developed, which lasted two or three days. On October 27th a scarlatinoid rash appeared on the chest, but was gone on the following day. No desquamation followed. A small amount of albumin was found in the urine on the same day. Urine was not examined for casts. The urine cleared up in four or five days. The swelling did not entirely recede until October 30th. There was decided weakness and anemia with the onset of convalescence, which lasted two or three weeks. On November 5th the left ear began to discharge, which continued for about three weeks. He was completely recovered by November 20, 1919. Treatment was symptomatic. On December 20, 1919, about one month after recovery, he developed typical bilateral mumps. The case of mumps referred to under diagnosis occurred on October 30th. On February 16, 1922, during the prevalence of the influenza epidemic in the territory, he developed the disease in relatively mild form. All the other members of the family, the parents and the infant brother, were also attacked with influenza, the father's case being complicated by pneumonia. The baby brother escaped the glandular fever but contracted mumps several days subsequent to the patient's case. This case was the most severe, as well as the most typical, of the series.

CASE II.—E. S., female, aged eighteen months. Was first seen on November 11, 1919. Had been sick for a day or two. There was fever, rapid pulse, fretfulness, coated tongue and constipation. Below the angle of the jaw and along the anterior border of the sternomastoid muscle two or three glands were enlarged and tender. Throat was clear. The fever continued for three days and the glandular swelling subsided on November 21st. The right side of the neck was not affected. There were no complications. The mother of this patient, aged twenty-three, gave a history of sore throat and enlargement of the glands of the neck about ten days previously. There were two other children in the same house, uncles and aunts of the patient, who escaped infection. The patient had moved before influenza reached the village, but all the members of the household who remained were affected with influenza. This patient lived about a quarter mile from the patient in Case I.

X Yes; — No; M bilateral; ♂ right unilateral; ♀ Left unilateral; O No test.

CASE III.—H. E., female, aged five years. First seen November 14, 1919, the second day of her illness. She had fever, anorexia, coated tongue, and some dysphagia. Below the angle of the jaw on the left side a swelling the size of a walnut was seen. The throat was clear. The glands on the right side of the neck became tender and enlarged on the following day, but did not attain the size of those on the left. The fever and other symptoms subsided a few days later, but the glandular swelling did not go down for several days. A sister of this patient aged seven years gave a history of fever and enlargement of the glands of the neck a week or ten days previously. No medical aid was sought. On November 14th all that was to be seen was distinct enlargement of the cervical glands on both sides of the neck. This girl in all probability had glandular fever and was the source of infection for her sister, but her case is not included in the series. There were no other children in this family. None of its members were attacked during the influenza epidemic. The house was situated directly across the street from that of the patient in Case II.

CASE IV.—S. B., male, aged six years. First seen on December 3, 1919, on the fourth day of the illness. Temperature was above 103° F., and there was dysphagia with stiffness of the neck. On both sides of the neck below the angle of the jaw and along the anterior border of the sternomastoid muscle

there were glandular swellings, two on the left side and one on the right, which were extremely tender to the touch. The swelling in this case was the largest in the series. Constipation and abdominal distress were marked. The fever subsided on the tenth day of the illness. The stiffness and tenderness lasted a week longer, and the swelling remained stationary for about three weeks. Convalescence was slow, with weakness and anemia.

COMMENT.

No assertion is made that the case histories given above represent a thorough study of the cases. The patients were seen irregularly, no laboratory examinations were made except the urinalysis in Case I. Enlargement of the liver, spleen and mesenteric glands was not looked for. Glandular involvement in other regions than the neck was not seen. The cases occurred in Rixford, a village in northwestern Pennsylvania. No other cases were seen by me in the other villages and countryside in that territory. The average duration of the disease was from two to three weeks. One patient was attacked by mumps one month, and with influenza three months, after recovery from the glandular fever. Another patient had had influenza nine months before, and three months after, the glandular fever. There was one case of mumps near the village soon after the beginning of the glandular fever epidemic and a few cases in town at about the same time as patient in Case I had it. The other features are shown in the table.

SUMMARY.

A local epidemic of six cases of glandular fever followed in two months by a widespread epidemic of influenza is reported. The literature on glandular fever is briefly reviewed and an analogy attempted of this incident and the occurrence of pestis minor in plague epidemics. Comparison is made between glandular fever, influenza, and plague.

CONCLUSIONS.

1. Glandular fever is a clinical entity.
2. Its chief features are cervical adenitis and a lymphocytosis.
3. It occasionally goes unrecognized.
4. The degree of its association with influenza is not determined but may be of some epidemiological significance.
5. Further blood studies in glandular fever is necessary as well as further investigation of its bacteriology.

Laboratory Findings in Encephalitis Lethargica and Their Relation to Diagnosis

By ROBERT A. KILDUFFE, A.B., M.D.,
Los Angeles, Cal.

Encephalitis lethargica is an acute contagious disease, the cause of which, so far as known, being an ultrafilterable virus present in the nasopharyngeal secretions, the portal of entry being probably the nasopharyngeal passages.

While the condition has been recognized as a distinct clinical entity only within the comparatively recent past, it has, in all probability, at times been confused in the past with other conditions involving the cranial nerves with a subsequent more or less common symptomatology. Among these may be noted, in addition to encephalitis lethargica, acute poliomyelitis, botulism, syphilis, and certain forms of food and drug poisoning (1).

Because of the difference in the treatment and prognosis of these varied conditions; because of the frequent diagnostic difficulties they present, and because of the important relation of the early diagnosis of encephalitis to prophylactic measures, it seems of interest to gather together the various laboratory procedures of possible value and to establish their evaluation and status with regard to this infection.

This seems of especial interest because of the presentday tendency to utilize, at times, laboratory methods at the expense of other methods of examination and to replace minute and exhaustive clinical examinations by laboratory requisitions.

The usual laboratory avenues of approach in encephalitis are the urine, the blood, and the spinal fluid, all of which may be considered in order, it being definitely stated at the outset that pathognomonic findings are present in none and that the findings in all must be carefully interpreted and closely correlated with all the other findings of the particular case.

URINE.

There are no characteristic findings. It is not infrequently entirely normal and, when variations from normal are found, they are, as a rule, such as are indicative of a mild, infectious nephritis. (2)

BLOOD.

Blood cultures have been, without exception, sterile in all reported instances and, if the cause of the disease is an ultrafilterable virus, as seems most probable, no information can be expected from this type of blood examination except where a secondary or concurrent bacteriemia seems possible.

Cytological blood examinations have, likewise, given little information of value *per se*. Neither the hemoglobin percentage nor the red cell count show any significant variations from normal. As a rule, there is no marked evidence of either leucocytosis or leucopenia, the white cell count varying from normal to 15,000 or 20,000, the average finding being generally a slight leucocytosis—10,000 to 12,000. Studies of the stained smear show little. The differential count in the presence of an increased number

of white cells shows the increase to be mainly of polymorphonuclear origin. Serological examinations of the blood in the absence of an antigen are not feasible.

SPINAL FLUID.

It is in the spinal fluid that the most marked variations from normal would be naturally looked for and it has, accordingly, been studied by numerous observers. It is, perhaps, advantageous to record the findings noted in order.

1. *Appearance.*—As a rule, the fluid is clear and limpid though slight degrees of turbidity due to increased cell content have been occasionally noted.

2. *Pressure.*—Normal, as a rule; when increased the increase is slight (2).

3. *Cell count.*—Normal or moderately increased. Neal (2) has occasionally seen the cell count reach 150 to the c.mm. Howell (3) in a study of thirty-eight fluids, reports counts ranging from 2 to 212 with a mononuclear percentage of forty to one hundred per cent. Other observers, though occasionally noting an increase in the mononuclear percentage, found the predominating type of cell to be the polymorphonuclear.

4. *Globulin.*—Usually slightly increased, the degree possibly bearing some relation to the stage of the disease in which the puncture was made. In any event, the increase in the amount of globulin is not apt to be marked.

5. *Sugar content.*—This has been studied by several observers. The average sugar content of 203 normal fluids is reported by Moates and Keegan (4) as 0.0588 per cent. and the same observers in a study of twenty-nine cases of encephalitis report findings of 0.046 per cent. to 0.288 per cent. They believe an increase of sugar to be of some diagnostic importance. The same view is expressed by Thalhimer and Updegraff (5). Neal (6), however, finds sugar determinations of no value.

6. *Complement fixation test.*—Uniformly negative except where there is coincident syphilis.

7. *Bacteriology.*—Uniformly negative.

8. *Colloidal gold reaction.*—Varying and contradictory findings are reported, all observers, however, being united in the opinion that there is no curve significant *per se* in this disease. The majority of observers find the changes to occur toward the left of the series or in the socalled syphilitic zone and frequently of the moderately luetic type. Negative reactions are common.

Davis and Kraus (7) in a study of thirty-four cases found an abnormal colloidal gold curve in forty-one per cent., the reactions generally occurring toward the left of the series. They were unable, however, to note any relation between the character of the curve and the duration and severity of the disease or the clinical picture.

Similar findings are recorded by Howell (8) and by Lewis, King, and Dinegar (9). The last named, however, feel that the occurrence of a luetic or paretic curve in the absence of a positive Wassermann in the spinal fluid coupled with the presence of suggestive clinical symptoms is of some diagnostic significance.

The occurrence of a paretic curve in encephalitis has been disputed but instances have been reported by Howell (10) and Davis and Kraus (11).

While a typical paretic curve is not a frequent finding the last named observers in thirty-four cases found the curve to vary from 5432211 to 0000110000 and similar readings have also been reported by others so that such a curve does rarely occur.

The following summary of colloidal gold reactions seems justified:

a. There is no characteristic colloidal gold curve in encephalitis.

b. The reactions, apparently, while indicative of meningeal irritation, give no indication as to the cause or type.

c. Reactions may vary from negative to moderate changes in the left of the series or in the socalled syphilitic zone; rarely these may be marked and may simulate the socalled paretic curve.

d. The character of the reactions appears to bear no relation to either the cell count or the globulin content of the fluid.

From the foregoing it is apparent that the diagnosis of encephalitis cannot be made by means of laboratory findings with any certainty; indeed, the differential diagnosis from poliomyelitis is almost an impossibility except by virtue of the more abrupt onset of the latter condition and the fact that it is associated in its inception with a decrease in the sugar content.

Laboratory examinations in encephalitis, however, if they have little positive value are of distinct negative value in aiding in the diagnosis of the disease by exclusion, and are thus of assistance in ruling out syphilis, the pyogenic meningitides, and tuberculous meningitis. As always, the true significance of laboratory findings is best determined by their correlation with all the other findings of a particular case.

Public Health Education

By ALGERNON BRASHEAR JACKSON, M.D.,
Washington, D. C.,
Professor of Bacteriology and Public Health, Howard University School of Medicine.

I wish to say at the outset that the ideas here projected are the result of inspiration rather than of experience, as my experience in the teaching of public health is limited. But after many talks with those who have been longer engaged in this field I find that they too are a bit vague as to the best methods which should be employed in public health education, so I shall not apologize for daring to have certain ideas.

So far, I am happy to say, the process of public health education has not been frozen over by an impermeable crust of standardization. This to my mind is the most hopeful sign, in that opportunity for experimentation, development and serviceable extension is not throttled, or embarrassed by dogma, cant and fixed policy. There is now no question as to the place public health will hold in future medical education and practice, yet a tremendous responsibility rests upon the shoulders of those who teach the subject to make that place definitely assured and practical. At present it is generally agreed that the place to start health education is in the public schools, to be continued and amplified throughout the college and university courses. Just here let it be recorded that physical education has come to be recognized as a positive ally to the health program, and coupled with lessons in hygiene, as it must be, gives to our schools and colleges a decided opportunity to awake within the student's mind his slumbering health consciousness. The future of public health in a great measure rests upon the ability of our teachers of physical education to vitalize health and make it both attractive and desirable by tactful presentation of the principles of hygiene. But it is my purpose to discuss public health education as touching the undergraduate and graduate physician.

In the first place, we face the fact that the majority of medical students, upon graduation, enter upon their life's work as general practitioners. Incidentally, they hope to make a good living out of their profession and in this they are justified. Many of them have chosen the medical profession because they believe it to be a good business. Many have suffered all sorts of financial sacrifices in order to earn their medical degree, and usually are heavily in debt. They see the members of the faculty drive up in sumptuous cars, find them living in luxurious homes, and hear the majority of them lecture on curative medicine, and at once come to the conclusion that it is curative and not preventive medicine that pays. The chair of public health in the medical school cannot and must not be expected to carry the whole burden in teaching preventive medicine. Unless the occupant of the chair is a wizard—and few are—he cannot do the job alone of making the subject attractive and hopeful to the average group of medical students.

The thing that happens in the process of most medical education is the emphasizing of sickness, the abnormal rather than the normal. Only too often it occurs that the student is drilled in recognizing the abnormal and almost nothing taught about the recognition of the normal. I have often observed that the dullest student can recognize the abnormal but does not and cannot recognize the normal, and even the brightest student is not far ahead of him when it comes to detecting the normal. This is a most serious defect in the methods of medical teaching and it is upon the basis of this faulty teaching that the student expects to find sick persons, and is usually successful. His one ray of hope is to find sickness.

The very word preventive medicine scares the student away, for to him it seems like financial suicide and as he emerges out of school he is not ready to kill the proverbial goose that lays the golden eggs. Frankly I do not like the word preventive as applied to medicine and in all my teaching I use the term sociological medicine when referring to public health practice and measures. It is possible that my term does not cover the ground, but after all, medicine today is becoming more and more the biggest sociological factor in the world and in my short experience I have found it easier to carry the thought to my students by the use of this term. There are no rights reserved and no patent, so any one who cares for it may use it, and others, too, if for no other reason than to disagree with it. The possibilities for discussion are great.

Not until we can get every member of our medical faculties to teach the methods of human betterment as applied to medicine, injecting therein the sociological phase of the physician's duty to the public, shall we be able to get our young physicians to catch the new spirit of the new day. Almost every physician in the world, from the most erudite specialist to the money mad practitioner, in various degrees advises his patients along sociological lines as touching health problems. It so happens with the majority that they do much of this work without seeming to regard the high plane such advice occupies in their daily practice. Those who teach dwell more upon the cures made than upon the sociological phases entering therein, and it is just here that the average medical student gets a onesided picture. Thus the young physician goes out into the world with the idea that his success depends upon sickness alone. Sickness we shall always have with us, but there are always more sick persons going about their daily occupations than are to be found confined to home and bed. The records of the last war opened our eyes to this important fact. As the public health idea spreads, this former class will make up the majority of our patients. As I have often noted, it happens that the public is becoming educated more rapidly in this phase of medicine than are the physicians, and it is our duty to see to it that practitioners are not caught napping.

In most instances public health teaching has been an outgrowth of the bacteriological department of our medical schools. Unquestionably this is the proper source of such ideas and practice, but it is easy to conceive the rather fatal limitations to which this vast subject may be confined by restricting it to this department. Many of the teachers of bacteriology have always been purely laboratory men and know little of the practice of medicine and its human touch. Far too often laboratory men are inclined to reduce everything to a formula and are prone to neglect the fact that human beings are not always, in fact never, quite so reducible. I do not believe it possible for any one to teach public health who has never been in close touch with patients and their medical and sociological problems. Nor it is possible to teach the subject properly without a workable knowledge of human psychology. The matter of human behavior and human reaction under the application of certain altruistic stimuli must play a positive part in the whole process or we miss the goal toward which we are striving. The human side after all is the big thing, the grand idea, and if we miss that we miss all.

More and more it must become the duty of all medical teachers to emphasize and dramatize the tremendous conservation program which is necessary to meet the stress of present day economics, and the part modern medicine plays therein. In the new light of thinking and acting it is imperative that every physician regard himself as a private health officer, and in this capacity administering to the sociological, economic and health needs of his patients and their families. There is no way to apply the principles of health and hygiene except through the family. Family habits and customs give us our cue. Society must be taught to want health and then to realize that certain rules must be obeyed to obtain it. In other words, public health must be made fashionable. In order to attain this end every physician becomes a teacher and incidentally he will find it a paying practice.

It has been my custom in lecturing to undergraduate students to emphasize the fact that the public health course given in the medical schools does not presume to teach them to become public health officers, but rather private health officers. My attempt is always to try in some way to develop the public health consciousness in the minds of young medical men and women. One lecture is given on the subject, Does Public Health Pay?, and in this the idea is stressed that the ordinary methods of public health practice, as they can be applied so well by every physician, afford a wonderful open sesame to the hearts, minds, and pocketbooks of the public, and is the young physician's one best opportunity. Experience has shown me that a lecture of this type sows the seed of desire to know more of public health and takes away from the subject the suicidal aspect which it at first seems to present to the mind of the average student. Put in plain, terse, idiomatic language, all young medical students "have to be shown," and they are not willing to take an interest in public health so long as it seems an idealistic matter which gives no financial returns. However, greater and greater strides are being made in public health every day as the people are beginning more and more to demand it and are willing to pay for it.

The American public today does not want state medicine, nor free medicine, but better medicine and better doctors. The practice of public health methods brings about both better medicine and better doctors, for it weeds out the incompetent and careless physician and lifts the whole matter of early and careful diagnosis to a higher plane. Training in public health methods makes good doctors, better doctors, and whether they serve in either a public or a private capacity, they are always able to render a higher and better service to the community than they who are not so trained and are therefore without the big vision of the greatest of all human services. There never was a time in the history of man when the thoroughly trained physician occupied the pivotal position in society that he does today. There is hardly any field in social economics that he does not touch and in most instances serves as a most determining factor in the proper functioning thereof. There never was a time in the history of education when the M. D. degree carried with it such a dignified and tremendous responsibility as it does today, typifying the highest and most serviceable academic attainment possible. Much of this result is due to the public health movement and the sociological application of those principles which bring a greater degree of health and happiness to mankind.

It must, therefore, become the duty of all medical teachers to join hands in perpetuating and amplifying the high principles already attained. There is no place in the curriculum in which the teacher cannot feel justified in stressing the advantages and importance of sociological medicine, with the idea of focusing the student's attention upon the ultimate high calling which is demanded by modern medicine. The physician has no one to blame but himself for the mushroom outcropping of the various "pathies" which have sprung into being because their projectors were shrewd enough to see that the public wanted the human touch, which regular physicians had too long withheld. But as sociological medicine grows we see born a new practice, a practice with a heart in it, a practice with a soul in it. This is the vision present day medical teachers must catch if they are to keep their standards at the ultimate, and invulnerable against the shafts of all classes of interlopers and impostors. It seems quite certain that the majority of our teachers are conscious of their duty and the tremendous responsibility which is theirs.

Public health is science brought to life and ushered into society. Sometimes we are too often inclined to make our science too literal, too dogmatic and never let it get a perspective and feel the touch of imagination, atmosphere, and that element of humanness it needs to make it practical. Public health is science put into play, into action for the preservation of society, and the development of the highest and best social instincts among men. If medicine is to hold human respect it must study human society more and serve it in a larger way.

Notes on a Group of Burn Cases*

By JOHN F. X. JONES, M.D.,
and A. P. KEEGAN, M.D.,
Philadelphia.

As a result of the explosion of a gas tank eleven laborers were more or less severely burnt and were admitted to St. Agnes's Hospital, October 10, 1922. The following notes are abstracted from the hospital records of these cases.

CASE I.—J. M., aged fifty, Italian; face, neck, both forearms, and both hands burnt in the second degree. His temperature was 101.4° on the second day, 102° on the seventh day, and gradually descended, reaching 98.4° on the ninth day. Pulse rate did not exceed 100. Rate of respirations varied between 18 and 24. Coagulation time of blood was six and one half minutes. Slight increase in the number of white blood cells (8,400 to the c.mm.). Two uranalyses showed albumin; six examinations were negative. Thirty fluid ounces of urine were voided during patient's second twenty-four hours in hospital. Patient was discharged on the eighteenth day.

CASE II.—L. D. S., aged twenty-four, Portuguese; face, neck, right and left arm, right hand and left leg burnt in the first and second degree. Temperature arose to 101.6°, gradually descended, and was 98.4° on and after the tenth day. Rate of pulse was 96 on admission and 80 when discharged. Respirations were 20 to 22. Eye complication, conjunctivitis. Coagulation time of blood three minutes: Leucocytosis of 16,600 to the c.mm. Urine voided during the second day measured thirty fluid ounces.

CASE III.—R. A., aged forty-six, Spaniard; face and neck burnt in the first degree; left arm burnt in the second degree. Temperature on the third and fourth days was 99°. The rate of the pulse varied between 70 and 80. Respirations were 18 to 20. When discharged the temperature was 98.4°, pulse 70, and respirations 20. Patient would not permit examination of his blood. On October 14, 1922, a twenty-four hour specimen of urine measured forty fluid ounces and contained no albumin, no casts, no acetone, and no diacetic acid. Discharged on the twelfth day.

CASE IV.—R. D., aged twenty-five, American negro; burns of first and second degree involving face, neck, posterior surface of thorax, and both forearms. Patient's temperature descended to 97.6° shortly after admission, but he reacted to external heat (electric cabinet). Patient vomited at intervals on the second and third days. October 7, 1922, patient complained of pain in abdomen, no tenderness, no rigidity. On October 18th, 19th, 20th, and 21st the patient was feverish (temperature 100° and 101°), restless and, at intervals, delirious. On October 22d, the temperature was 98.8° by axilla. Patient had improved. Coagulation time of blood was four minutes; white blood corpuscles 6,050 to the c.mm. Twenty-four hour specimen of urine measured thirty-three fluid ounces. Eye complication (conjunctivitis) was present. Ten specimens of urine contained albumin; four were free from albumin. Discharged on the thirtieth day.

CASE V.—F. D. G., aged twenty-eight, Italian; second degree burns of face, ears, arms, forearms and hands. After admission patient's temperature dropped to 96°, and he was placed in the electric chamber, where he reacted. Coagulation time of blood was five minutes; leucocytes 9,500 to the c.mm. Eye complication, conjunctivitis. Four specimens of urine contained albumin; six specimens were free from it. A twenty-four hour specimen measured thirty-five fluid ounces. Patient was discharged on the thirtieth day.

CASE VI.—J. M. A., aged twenty-eight, Portuguese; face, neck, posterior aspect of chest, and both upper extremities burnt in the second degree. On admission temperature was 99° and then became subnormal. Patient reacted in the electric chamber. Maximum height of temperature was 102.6° (on fourth and ninth days). Pulse was 112 on tenth day. Eye complication, conjunctivitis. Coagulation time of blood, seven minutes. Leucocytes, 7,800 to the c.mm. Twenty-four hours urine output measured forty-eight fluid ounces. Eight specimens of urine contained albumin and five were free from albumin. Patient was discharged on thirty-fifth day.

CASE VII.—G. T., aged twenty-six, American negro; burns of first and second degree involving face, neck and both arms; severely infected. Temperature arose to 104.6° on the fourth day, but descended to normal on the ninth day. Eye complication, conjunctivitis. Coagulation time of blood, five and a half minutes. Leucocytosis, 7,000 to the c.mm. Twenty-four hours output of urine measured twenty-four fluid ounces. Several examinations of urine revealed albumin. Patient was discharged on the eighteenth day.

CASE VIII.—P. S., aged thirty-two, Irish; first and second degree burns of face, neck and arms; temperature ascended to 102° on the second day and returned to normal on the seventh day. Eye complication, ulcer of cornea. Coagulation time of blood, four minutes. Leucocytosis, 11,100 to the c.mm. Twenty-four hour output of urine was seventy fluid ounces; several specimens contained albumin and casts. Patient was discharged on the eighteenth day.

CASE IX.—A. F., aged thirty-six, Italian; face and left forearm burnt in the first degree. Coagulation time of blood, five minutes. Leucocytosis, 9,900 to the c.mm. Patient voided seventy fluid ounces in twenty-four hours. Discharged on the fourth day.

CASE X.—E. G., aged twenty, American negro; left arm burnt in the second degree. Coagulation time of blood, three minutes. Leucocytes, 9,000 to the c.mm. Twenty-four hour output of urine measured forty-eight fluid ounces. Patient was discharged on the third day.

CASE XI.—F. C., aged twenty-two, Italian; first degree burn of face; first and second degree burn of

*Meeting of Clinical Staff, St. Agnes' Hospital, Friday evening, February 23, 1923.

right hand. Coagulation time of blood, four minutes. Leucocytes 13,100 to the c.mm. Patient voided forty-eight fluid ounces in twenty-four hours.

TREATMENT.

On admission to the hospital each patient received an injection of a quarter of a grain morphine and an inoculation of 1,500 units of tetanus antitoxin. For the first seventy-two hours sterile gauze dressings, saturated with a ten per cent. hot solution of sodium bicarbonate, were applied to the burnt areas. As soon as it could be obtained, a specimen of urine from each patient was sent to the laboratory to be examined for albumin, casts, diacetic acid and acetone. After the initial specimen had been secured, the daily twenty-four hours output was measured and sent to the laboratory for examination. This report mentions only the result of the examination of the first twenty-four hours specimen of urine from each patient. The first twenty-four hour specimen has been secured in most of the cases within forty-eight hours; in a few, within seventy-two. We feel that it is important quickly to examine a specimen of the first urine procurable, as we do not wish to be delayed twenty-four, thirty-six or forty-eight hours if we are dealing with acidosis.

Internally, to these patients were administered coffee, potassium citrate, calomel, magnesium citrate, and abundance of water and concentrated liquid nourishment. For one man in whom we suspected (fortunately, without foundation) acidosis we ordered bicarbonate of soda by mouth and by bowel—without waiting for the result of the uranalysis. Three of these patients were placed in electric cabinets because of subnormal temperature. These three patients also received atropine hypodermically and whiskey by mouth. After seventy-two hours had elapsed the sodium bicarbonate solution was discontinued locally and the burnt regions were kept moist by means of a two per cent. solution of Dakin's oil. We realize that a two per cent. solution of this preparation may be irritating to some patients, but this group of patients did not seem to suffer any pain from it. The eye complications were treated successfully by Dr. George F. J. Kelly. When these patients were discharged from the hospital their burns had either completely healed or had been covered by healthy granulations.

We are not interested in advocating any one particular method of treating all burns, but we believe with Lee (1) that sealing burns with wax is comparable to closing traumatic wounds and we accept Moorhead's (2) definition of burns, namely, "infected wounds due to heat."

Anemia Subsequent to Antisyphilitic Treatment

By LOUIS STERN, M.D.,
New York.

The association of anemia with syphilis has long been recognized. Only recently, however, has any attention been given to the anemia which follows the clinical cure of syphilis, or an attempt made to ascertain whether the impoverished condition of the blood was due to the natural effects of the spirochetic infection, or could in any way be related to the drugs administered to combat this infection. It has always been customary to regard the anemias of syphilis as of relatively small importance, and in like manner, when the condition appeared subsequent to a course of antisyphilitic treatment, it received only cursory attention.

That postsyphilitic anemia may, however, become a grave, and occasionally even fatal condition, has been brought home to us by several recently reported cases of aplastic anemia following the administration of drugs of the arsphenamine group. Two years ago Hans Görke, of the University of Breslau, gave an account of three cases of aplastic anemia following salvarsan administration, two of which were fatal. A fatal case of stomatitis and aplastic anemia due to neoarsphenamine was published last year by Moore and Keidel, of Baltimore, and a few months ago Feinberg, of Chicago, reported another with a similar history. Feinberg remarks that he was moved to publish his case because of the rarity of such accounts in the literature, and also "because it points out one of the possible complications of neoarsphenamine, which has thus far been chiefly overlooked."

Though simple anemia is not a rarity either during or following a syphilitic infection it is none the less true that it, also, has been chiefly overlooked. This point was effectively brought out in a symposium on visceral syphilis which was featured at the annual convention of the British Medical Association in 1921, where John Eason discussed the anemias of syphilis. As the anemogenic processes of syphilis are very imperfectly understood he felt that writers generally had succeeded only too well "in instilling the idea of mildness as being almost characteristic of this anemia" while as a matter not only of his own observation, but of record in the literature, "the anemia occurring in secondary syphilis may be grave, or even fatal."

The frequency with which the spleen is involved in a general syphilitic infection—most often without manifesting any symptoms whatever—has been emphasized by Wile, although at the same time he pointed out that anemia occurring early in the course of the infection might be generally constitutional, rather than splenic in origin. Many of Eason's cases of secondary syphilis showed a severe degree of oligocythemia, as well as poikilocytosis, anisocytosis polychromasia and punctate basophilia. There were normoblasts and megaloblasts, and in one case, eosinophil and neutrophil myelocytes were found in con-

siderable numbers. In all the cases the color index was definitely above one, with a red cell count of 1,000,000 and about twenty per cent. hemoglobin, with grave anemia.

It is unfortunate that more extensive records of different blood pictures in syphilis are not available, for their comparison with those obtained after a course of treatment with one of the arsenical preparations might bring to light some interesting considerations.

I have had no opportunity of seeing any such severe cases of postsyphilitic anemia as those described by Moore and Feinberg; but in the routine of practice so many patients come under observation who are suffering from profound blood derangement following the use of arsphenamine or neosalvarsan for the treatment of syphilis that the frequency of the condition has been very forcibly demonstrated. Assuming the prevalence of anemia due to the spirochetic infection, the question naturally arises, as to how far we may attribute the condition which we find after a course of drugs of the arsphenamine group to the original infection, or whether any particular case may not be wholly due to the toxic effects of the drug.

The truth is that little is known of the actual pharmacology of arsenic, outside of clinical demonstration, and in the minds of many physicians there is considerable confusion as to whether the value of salvarsan lies in its actual spirocheticidal ability or in the assistance in building up the resisting power of the blood, thus enabling the body to effectually overcome and neutralize the invading organisms. This confusion dates back to the period when salvarsan was first commercialized, and is largely due to the misleading propaganda put forward at that time by certain producers. Because of this confusion many practitioners fail to distinguish between a tonic dose of an arsenical derivative, and the spirocheticidal dose.

As Kiefer has recently expressed it: "We must always bear in mind the fact, as originally pointed out by Ehrlich himself, that the action of salvarsan on the spirochetes is not that of a direct spirocheticide, but that a third factor existing in the body fluids is necessary, which appears to be a fixing agent comparable in a general way to the action of complement (which is nonspecific) but which acts to complete the antigen amboceptor combination."

Elsewhere, this same writer remarks that because of "the apparently wonderful results" following the use of salvarsan, we are too often tempted "to treat syphilis, rather than patients with syphilis, and to formulate definite courses of treatment" without observing that "while the disease is being influenced quite as favorably as we would have it, the patient is retrogression physically."

The soundness of these observations has been repeatedly demonstrated in my personal experience, and the necessity of considering each person who comes for treatment, not as a case, but as an individual patient, subject to the infinite variations from type likely to be in evidence in every member of the human race, has become increasingly manifest. In many cases, the sequel of vigorous treatment with neoarsphenamine and mercury has been a profound anemia, and recovery cannot be hoped for unless the hemoglobin index, and red cell count, can be increased. The depleted state of the blood indicates how greatly the patient's general powers of resistance have been lowered, and demonstrates the occurrence of some change in the blood and body fluid which has affected colloid exchange.

Once we are assured that the anemic condition is the result of the mercury and arsenic being thrown into the circulation, the only rational procedure would appear to be, to substitute some other form of medication, at least until such time as an increased red cell count indicates that the anemia is under control. But if the Wassermann reaction is still positive, very few of us have the courage of our convictions sufficiently to permit us to withdraw these two standard antisyphilitic agents, or even—as Kiefer suggests—combine them with iodides, as more applicable to this particular patient's blood findings.

In a previous paper I reported a number of cases where I had been successful in correcting anemia by means of iron and arsenic intravenously administered. Since the appearance of that article I have applied this form of treatment much more extensively, and can confirm and reiterate all the observations which I made upon it three years ago. Not only am I even more firmly convinced of the value of this form of therapy in many blood conditions, but I regard it as peculiarly applicable to the particular type of anemia here considered, the anemia following antisyphilitic treatment by neoarsphenamine and mercury.

There is today no need of giving any details for the technic of administration—the use of the intravenous route is now too frequent to make that necessary—but there is one point which it is still desirable to emphasize—and that is the purity of the solutions used, and the accuracy of the dose. In the intravenous treatment of anemia we are adding certain elements directly to the blood stream, and thus passing them by the shortest possible route into the blood forming organs. There is no room for guesswork, nor haphazard measures, so it becomes essential that we employ only standardized biologically tested solutions prepared with the most minute accuracy. To the practitioner who exercises care and thoroughness in this regard, success is practically certain. This particular solution of iron and arsenic, sixty-four mgs. (one grain) of iron cacodylate in five c. c., is contained in a glass ampoule. The iron is in a colloidal state.

Before reporting a few cases illustrative of the points I have endeavored to bring out, it may be well to outline my usual procedure in the routine treatment of syphilis. I regularly employ neoarsphenamine giving a series of six injections at weekly intervals; following the course of neoarsphenamine injections mercury oxycyanide is given twice a week—intravenously, eight mgs. (one eighth grain) in a five c. c. solution. The mercury oxycyanide is continued for at least a month, after which the patient is given a month's rest, with no medication of any sort. A second series of neoarsphenamine injections occupies the next six weeks, again followed by a month of intravenous oxycyanide treatment and a month's rest, and this program is repeated until the Wassermann reaction regularly remains negative.

During the course of such treatment, and after the Wassermann reaction has been negative for some time, I have frequently found a low hemoglobin index, often associated with symptoms which might readily be regarded as reflexes from the central nervous system. To combat these conditions I have used intravenous injections of a solution of iron cacodylate—sixty-four milligrams (one grain)—administered at four or five day intervals. I have found that the cacodylates are ideal compounds to employ when one wishes to obtain the tonic effect of arsenic, and it is surprising how soon the socalled nervous symptoms disappear, when the blood content shows improvement.

Case I.—This patient, an automobile salesman, had had a primary chancre in the urethra, the scar of which could be seen with the urethroscope at the time he presented himself with a secondary eruption. The Wassermann reaction was positive—four plus. Treatment with neoarsphenamine followed by mercury oxycyanide, according to the plan above outlined, was instituted. Anemia was very evident, the red cell count being 3,680,000 and the hemoglobin index 68. To improve the blood condition twelve intravenous doses of iron and arsenic—one grain in to five c. c. solution—were given at five day intervals, following which the red cell count mounted to 4,800,000 and the hemoglobin increased to 95, while the patient had gained eight pounds in weight.

Case II.—An actor, who had served in the navy for a year during the war. Initial lesion had occurred while he was in service, and he came for treatment of active secondary manifestations the original scar being evident and the Wassermann reaction four plus. He was put on the routine treatment of neoarsphenamine and mercury oxycyanide, but anemia and neurasthenia were so profound that he was unable to do any professional work. The red cell count was 3,600,000 and the hemoglobin 75. After fourteen intravenous injections of iron and arsenic given at five day intervals, the neurasthenia disappeared, there was a decided gain in weight, and the patient was able to go back to his work. The final blood count was: red cell, 5,200,000; hemoglobin, 100.

Case III.—Pugilist, aged twenty, returns from service in the trenches with a history of an initial lesion of the left tonsil—condyloma, the Wassermann reaction being three plus. After two successive courses of neosalvarsan and mercury oxycyanide intravenously, he lost weight, and was unable to keep in training. The hemoglobin had dropped to 80, and the red cells were only 4,000,000. After sixteen intravenous injections of iron and arsenic he regained his normal weight and was able to take up training again. He has since successfully engaged in a number of ring contests.

Case IV.—A nurse who had returned from the front gave no history of luetic infection, and no evidence of an initial lesion except induration of the posttonsillar tissue. The Wassermann reaction, however, was four plus, and a persistent cough was present. The usual routine of neoarsphenamine and mercury oxycyanide was instituted, but the patient was very much run down and anemic, the red cell count being 3,400,000 and the hemoglobin 75. Complete recovery followed the administration of twelve injections of iron and arsenic, the patient gaining twelve pounds in weight and becoming able to take up teaching, continuing in excellent condition.

Additional case histories and a bibliography will appear in the author's reprints.

Functional Manifestations Associated with Organic Neurological Diseases in Exservice Men*

By JOHN H. BAIRD, M.D.,
New York,
Passed Assistant Surgeon, (R), U. S. Veterans' Hospital No. 81.

Manifestations of functional disability comprise by far, the largest group among the neuropsychiatric cases in exservice men. Organic disease, with its usual freedom from functional symptoms of any consequence is the rule, though in a certain proportion of instances functional and organic disturbances coexist. The general principles laid down in this paper are meant to cover all organic diseases, though the case illustration which is to be presented has to do primarily with the combination of functional symptoms with organic central nervous system disease.

In many cases the functional element is more extensive in distribution than the underlying organic part, and, as it were, submerges it. Unless great care is exercised in the examination, the organic factor may be either overlooked and the whole case wrongly regarded as functional or else the organic paralysis defect may appear more serious than it really is.

It has been frequently observed that persons with gross bodily injury or disease very seldom present symptoms of a functional nature. It seems plausible therefore to admit that serious bodily injury protects the patient to a certain extent against a traumatic neurosis. Such patients know positively that their disability entitles them to an indemnity and they do not have to worry about money damages, or else the presence of the individual's own serious disability occupies so completely the field of consciousness that there is no room for subjective phenomena to be added by suggestion. Such a state of affairs, however, does not exist ordinarily at least, in cases of an organic character with comparatively slight intrinsic disability.

The apparent individual organic reaction must of

*Publication authorized by the medical adviser, U. S. Veterans' Bureau. Read before the New York Society for Clinical Psychiatry, April 12, 1923.

course not be underestimated, but in addition to this there is the ever present individual mental attitude toward the disease process which plays a prominent rôle in the symptoms, outlook and treatment of such cases, but chiefly those which are destined to be chronic. Dr. Louis Casamajor, in an address before the New York Physicians' Association, in February, 1920, summed up the situation as follows: "Disease, and more especially chronic disease, is an added experience element in the life of the patient, and one that must be considered in his adjustment to his life, both present and future."

So we may find that an actual structural disease of the central nervous system, for instance, may and often does serve as a convenient and indeed natural foundation upon which to build a vast number of functional symptoms. This array of functional complaints, though not at all a part of the organic defect, may and often does become more of a real burden to the patient than those symptoms resulting from the original organic disease. Only too frequently these functional signs are disregarded as of no real importance and our patient continues to suffer mentally more than physically. Failure to recognize their existence, therefore, gives us only half the picture. Furthermore, the functional symptoms are the very ones that offer the greatest hope of alleviation. Misdirected treatment, however, such as daily massage for an hysterical paralysis of an extremity, for instance, would do more harm than good. Disabilities of a functional nature may therefore become so firmly fixed that recovery may be absolutely prevented or at least delayed.

Such patients are often influenced by their friends as well as by other patients and indeed by physicians themselves that their disabilities are permanent and that they never will be entirely well again, so that the problem increases in intricacy. The resultant difficulty is then, the problem of making an adjustment to the circumstances in which the man finds himself. The obstacles to be overcome are at least partially linked up with the circumstances themselves, but are to a much greater extent dependent upon the personality reactions of the patient himself. It is obvious, therefore, that our study of such individuals must continue along the lines of personality investigation.

The personality, as we know, is dependent partly upon inheritance and partly upon life's experiences and education as well as alterations in the physical field due to accident or disease, to which the patient has been exposed during life. It follows, then, that no neurosis, which is in reality a personality deviation, can be attributed to any single thing.

Given, then, an individual with a certain type of personality, in whom has been demonstrated a chronic central nervous system disease, with relatively slight disability resulting directly therefrom, we may discover a number of superadded neurotic or personality symptoms which often screen the symptoms of the original organic condition.

These neurotic symptoms are, in essence, a way out of an intolerable conflict. It becomes necessary for the patient to express himself anew. He is disabled organically, but in order to satisfy his own understanding of his condition, and also to permit others to understand, he must project additional symptoms to compensate for his feeling of personal inadequacy. In this way he attempts consciously or unconsciously to create a happy medium in his mental sphere, to find his level, so to speak.

The element of sympathy for one's plight also plays a not unimportant rôle. Compassion for one's own infirmities is innate in all and must be thoroughly understood by the physician in his comprehensive study of the nervously disabled. The actual source from which these superadded symptoms are derived is suggestibility.

The question of there being a underlying neuropathic basis in some of the cases of this type, the organic neurological conditions serving as the stimulus to bring forth an hysterical reaction, destined to come to the surface at some later time, without the acquisition of an organic disease, must be borne in mind.

Another and perhaps the most important element among the etiological factors in the production of neuroses in exservice men is the problem of compensation. This phase of the subject is of extreme national economic importance, for the number of compensated patients among the war disabled is rapidly increasing. The method of compensation, by which the patient receives a monthly allowance during the period of disability, would in some cases certainly seem to act as a stimulus to the prolongation of a disability in one with previous nervous instability. In others the fear of becoming helpless if work is resumed and compensation stops, together with the certainty of State aid if their disabilities continue, there is created a condition intolerable to the patient. Confirmed invalidism is consequently often the result.

It is my intention to attempt an analysis of the functional symptoms in an exservice man with organic disease of the central nervous system and to suggest possible inroads to their origin and nature.

The case selected, as an illustration, is a young man, aged thirty-two, single, formerly an accountant by occupation, a Catholic and born of American parents. His family history was negative. The essentials of his personal history are: apparently normal development, mental and physical, and no serious illnesses or accidents prior to his present trouble. He was graduated from Union College with an A. B. degree at twenty-two, having paid nearly all of his expenses by working at odd hours and during the summer months as a reporter for several newspapers. Immediately following his graduation he took a short course in accountancy and worked in this capacity for one firm for over three years, until his induction in the army on September 21, 1917. He was very fond of his work and apparently was successful. His salary was $260 a month. In makeup patient has always been frank and open and his adaptability prior to the beginning of his present trouble was excellent. His habits have always been moderate in all fields. Heterosexual relationship began at sixteen and had been very infrequent since. Venereal diseases were denied.

He was admitted to this hospital in December, 1922, complaining of an inability to read, loss of vision to the right of the midline, difficulty in walking, due to weakness of the right leg, weakness and awkwardness of the right hand and arm and numbness of the entire right half of the body, with actual

diminution in sensibility on that side, including face, neck, thorax, abdomen, arm and leg. He complained also of some loss of weight, without cardiorespiratory or gastrointestinal symptoms and displayed a real anxiety over his condition, manifested by a vague fear that he might be a mental case and also that he might never recover his former state of mental and physical wellbeing.

The onset of the organic neurological condition dated back to three weeks following an attack of cerebrospinal meningitis in October, 1917, while the patient was in an army camp. (His military history is essentially the history of the beginning of his present trouble. He was inducted on September 21, 1917, and was discharged on October 23, 1917. The records show that he was taken suddenly ill with high fever, headache, nausea and vomiting, pain and stiffness in the neck muscles and finally delirium with several days of complete unconsciousness.) During convalescence the patient asked for a newspaper and suddenly found that he was unable to read and coincident with this discovery he became conscious that he was blind to all objects in the right half of his field of vision, and also he noticed that he began using his left hand almost altogether in reaching for things and in eating, in spite of the fact that he was right handed. A day or two later, on attempting to walk, he found that his right leg was considerably weaker than the left and that it dragged somewhat during locomotion. All of these symptoms were well established before he was given a surgeon's certificate of disability from the Army and returned to his home on October 23, 1917.

At this time he began to have intense headaches, which persisted off and on for about a year and then disappeared entirely. Remaining at home for one month he went to Lake Placid for a rest, staying there until November of the next year, 1918. It is of importance to mention at this point that the patient had been engaged to be married but owing to his inability to earn a living and also to the fact that he had accumulated only a limited amount of money, he was forced to break his engagement. It is also of significance that he was as yet receiving no compensation from the Government. While at Lake Placid, in January, 1918, shortly following the breaking off of his engagement, and about three months after the onset of the alexia, hemianopsia and hemiparesis of the right arm and leg, he accidentally discovered that sensation had become markedly impaired over the entire right half of his body. This was brought to his attention one day, while walking through a doorway, when he bumped against the wall with the right shoulder and arm and was seized with the sensation of numbness over the entire right side. Ever since then, he maintained that sensation had been definitely less acute over the right half of the body. By July of that year, 1918, his Government compensation had been adjusted to a temporary total rating which was made retroactive covering his period of disability. Leaving Lake Placid he accepted a position as timekeeper for a corporation in Erie, Pa., earning $125 a month. Continuing in this for thirteen months, until December, 1919, he became enrolled in a course in accountancy at New York University, under the Federal Board. With his previous experience, together with his earnest desire to advance in his work and to overcome his deficiency, he remained until April, 1920, when he felt that he had to give up. He stated that "his resistance had collapsed and that his visual defect would never permit of his continuing." Abandoning the course he returned to Lake Placid, in April, 1920, where he regained a considerable amount of courage and built up his general physical health which had become undermined. In September he again attempted a course in accountancy at the New York University, but this time he remained only three months. Having been ordered before a medical board he was adjudged not feasible for training and was sent to the United States Veterans' Hospital in Perryville, Md. Remaining there for six months he returned home and was admitted to this hospital last December. In February, 1922, the patient's compensation was cut from $80 a month to $8 and this is the amount he is receiving at the present time.

Physical examination reveals good development and no malnutrition. Aside from a few missing teeth, x ray evidences of a mild, chronic bronchitis and clinical signs of a slightly overactive heart, the general physical status was negative. The neurological findings were as follows: equal, regular and moderately dilated pupils, which react rather sluggishly to light and normally to accommodation; no nystagmus and no extraocular palsies. Slight diminution of the corneal reflex on the right; complete right homonymous hemianopsia, with general narrowing of the visual fields, but without changes in the optic discs; right sided facial paresis, cortical in type (definite flattening of the right side on showing the teeth, but with fair preservation of emotional expression); tongue protruded to the left; without atrophy; weakness of the right arm and leg, without ataxia; right grip—30.5 kilos., left grip—53 kilos. Biceps and triceps reflexes greater on right; knee jerk and ankle jerk greater on right; abdominals present and active, less active on right; plantar stimulation, no response on right and marked plantar flexion on left; Babinski, negative bilaterally, unless the absence of any sort of response on the right was of significance in this regard; Oppenheim and Gordon negative; stereognostic sense normal on both sides; no speech disturbances. There was hypesthesia over the entire right half of the body, including the face, cornea, tongue, mucous membrane of the buccal cavity, the neck, trunk, arm and leg. This blunting of sensation included light touch, pin prick and thermal stimuli. It produced no inconvenience or loss of function. Joint sense, vibratory sense and point discrimination were unimpaired. Patient was perfectly able to recognize the posture of the affected extremities and their distal parts, the fingers and toes, when moved in space, while the eyes were closed. The sensory diminution stopped sharply at the midline of the body.

The patient had no difficulty in understanding spoken words and sentences and he could execute simple commands and complicated movements. He recognized and named objects correctly and could repeat words, phrases and sentences unusually well. He apparently encountered no difficulty in finding proper words to express his thoughts, and stream of conversation was always well connected and to the point. Reading showed a marked defect. He was

unable to read a sentence or complicated words. While attempting to read words he always picked out each letter separately and then combined them and in such a way he was able to identify a few short commonly used words, such as "the," "is" and "fine," but he failed completely to recognize the more complex words. All the letters of the alphabet were singled out correctly but quite slowly. The patient had difficulty in naming several of the figures, mistaking "8" for "3" and vice versa and "7" for "9" and as a consequence made frequent mistakes in addition, subtraction, multiplication and division. Tests in mental arithmetic were, however, promptly performed. He was able to copy sentences, letter by letter, in a laborious manner, but was entirely unable to read what he had written. Spontaneous writing and writing from dictation were prompt and quite well done. Such signs as Y. M. C. A., R. S. V. P., C. O. D., and U. S. A. were correctly identified. The writing itself was entirely lacking in character and had no uniformity. There were no apraxia.

Mentally, the patient was intelligent and presented no evidences of a psychosis. His memory was acute for both remote and recent events. Spontaneity of action and intellectuality were adequate and satisfactory and his adaptability was unimpaired. His general mental attitude and behavior were quite normal. He stated that he was not depressed at the present time, but was quite sanguine over the future, yet at the same time he stated that he was far below par generally and hardly knows what move he would make in the event he was discharged from the hospital without adequate compensation.

The blood Wassermann on several occasions, both before and after the administration of a provocative salvarsan, was negative. Spinal fluid revealed no abnormalities. Basal metabolic rate was minus eight per cent. (within normal limits). Complete blood chemistry, including blood sugar, urea nitrogen, nonprotein nitrogen and carbon dioxide tension disclosed no deviations from normal. There was slight secondary anemia at the time of admission in December, but this has disappeared. Gastrointestinal examination was negative. Renal function test and urinalyses were negative. Ophthalmological report was: vision 20/40 right and 20/40 left. Central vision good. Right homonymous hemianopsia, with marked contraction of remaining halves of the fields for form and colors. Stereoscopic examination of the skull was negative.

In the interpretation of this case we have, on the organic side, an individual with no signs of lues or cardiac disease, developing a complete right homonymous hemianopsia, with alexia, together with a right sided organic hemiparesis, subsequent to an attack of meningitis. Following the differentiation of Dejerine, referred to by Dr. Casamajor, in his report of a similar case, the form of alexia with which we are dealing is called "pure alexia" or "pure word blindness," with the preservation of writing, both spontaneous and on dictation. In such cases it is believed that the lesion is situated under the cortex of the angular gyrus, destroying the association fibres between the optic centre and the angular gyrus, which prevents the understanding of written words. The lesion, however, does not destroy the centre itself or the path from it to the writing centre. Such a lesion is nearly always accompanied by right sided hemianopsia. The nature of the lesion in this instance is probably that of a degenerative change in the nervous tissue in the above mentioned location, consequent upon the meningitis infection. The hemiparesis, which is also organic, must be accounted for by the existence of a separate and distinct cortical lesion of probably the same pathological nature.

On the functional side we were dealing first of all with a well educated young man, whose early development was normal and whose adaptability to society in general was excellent. No particular inherent idiosyncrasy in the type of gross emotional reaction, sexual or otherwise, could be elicited. Briefly then, the longitudinal section revealed a young man, formerly efficient and contented, but suddenly made inefficient, according to the standards set down for him and confronted with the problem of an entirely new adjustment. We have traced the development of rather sudden, spontaneous numbness confined to the right side of the body, namely, the organically affected side. It is suggested that the need for this superadded symptom may have arisen from the patient's conscious or unconscious desire to express the idea that his organic condition had produced within him, in clearer terms to himself and to others.

At the time this symptom was noted the patient was convinced that he labored under a tremendous handicap. His feeling was one of intense personal inadequacy. We will recall that he was at Lake Placid at the time, making a business of looking after his health, which in itself at least favored an introversion of interests. He was undernourished, he had almost constant headache, his vision was seriously impaired, he was unable to read and he felt that all his education had been acquired in vain. Furthermore, he had the fear that he might become entirely blind and therefore completely disabled and he even harbored the idea that he might become a mental case. On the more personal side, there is no question but that the breaking off of his engagement contributed its part in the formation of the source of the neurosis. Suggestion for the making of the superadded functional symptoms undoubtedly came also from the fact that he was receiving no Government compensation and from the realization that his finances were nearly spent. Following this patient's subsequent behavior we find him working as a timekeeper, simply because he wanted to occupy his mind at something, although he was then receiving a temporary total indemnity from the Government. This occupation was a compromise at best. It was not satisfactory, for there was very little in such work to stimulate real interest. Buoyed up by a false conception of his abilities to continue vocational training in accountancy, he failed utterly and this disappointment gave rise to more anxiety in an already hypersuggestible state of mind. His having been found not feasible for training, followed by six months' hospitalization, together with a reduction of his compensation from temporary total to ten per cent., capped the climax and his neurosis became more or less fixed. It is reasonable to assume then that the residua of the attack of meningitis was the activating agent in breaking down this patient's resistance and in causing the outcrop of the hysterical reaction.

Eczema of the Breast

By DOUGLASS W. MONTGOMERY, M.D.,
and GEORGE D. CULVER, M.D.,
San Francisco, Cal.

In a most entertaining and instructive paper on eczema of the breast, R. Sabouraud draws attention to a classification employed by the older French clinicians, who used to say that this affection occurred in this situation in three classes of patients, in those who had scabies, in those who were pregnant, and in the lymphatic (1).

The term lymphatic was applied to young people seemingly well nourished and apparently in good or even flourishing health. They had, however, a delicate, fine white skin, subject to infection, and cutaneously they were never out of trouble. The term as here employed must not be confused with the more recently developed designation, the status lymphaticus.

This grouping together of the scabetic, the pregnant, and the lymphatic has no pretensions whatever of being scientific, but its practical advantages are, as pointed out by Sabouraud, decidedly great. For instance, a young girl presents herself with this distressing difficulty, and the first question that arises is: Has she scabies? This question may be easy of solution. On the other hand, it may not be at all easy, as in modern city life the disease may be modified in many ways by inadequate treatment or by the use of antiseptic toilet articles. In fact, we ourselves, although constantly seeing diseases of the skin and always on our guard, consider scabies one of our most tricky diseases to diagnose. If scabies is satisfactorily eliminated, pregnancy may be considered, but of course, with the utmost tact, as by inquiry in regard to menstruation and observation of deepening of pigmentation of the nipples. Then there are the very rare cases of eczema of the breasts in young girls with the lymphatic disposition. The immediate cause of the eczema in all three classes is the streptococcus. Scabies, pregnancy, and the lymphatic constitution are predisposing causes.

Fig. 1.—Scabies of one breast in an unmarried girl, showing an unusual anatomical deformity.

There are still other cases of streptococcic infective eczema that occur in mature women with a strong vigorous constitution, and who are neither scabetic nor pregnant, but these are rare, and we later shall cite two examples of it in this paper.

SCABIES OF BREAST

Case I.—An unmarried woman, twenty-two years of age, called complaining of distressing itching all over the body, most severe at night. To the direct question if the nipples were affected she replied that the left one was. The nipple and areola were covered with thick impetiginous crusts, and there were scattered lesions over the surface of the breast with deep scratch marks. Curious to relate, the other breast was unaffected. The affected breast was very pendulous, while the other one was virginal and shapely. Whether the greater susceptibility of the left breast was in any way connected with this deformity could not be determined.

The affection had begun six weeks previously on a trip to Los Angeles with a girl friend. Both seem to have caught the disease: Now that the patient had returned home her mother had begun to itch also. Besides the trouble on the left breast, some old indistinct runs were found between the fingers, evidently with the contents killed by a previous, badly applied, ineffective treatment. A five per cent. creolin salve cured the disease.

ECZEMA OF THE NIPPLE IN A LYMPHATIC WOMAN.

Case II.—The patient was an unmarried school teacher, twenty-two years of age, a delicate, thin, anemic woman, with a decidedly seborrheic type of skin. She first consulted us in July, 1911, for a seborrheic eczema of the fingers, and she had redness across the bridge of the nose just above the tip, and blepharitis marginalis. She suffered from blackheads, oily seborrhea of the scalp, excessive sweating of the palms and axillæ, and she had a delicate white skin subject to branny desquamation. Unfortunately, her school room was a damp basement, especially unsuited to her constitution, susceptible to catarrh.

Her maternal grandmother and two maternal aunts died of consumption, and her father grew grey at an early age and died of cerebral hemorrhage. Her mother suffered from diabetes in her early sixties, and died from its effects. The patient's antecedents, therefore, were anything but fortunate. Her sister, who did not have eczema of the nipple, but was constantly subject to cutaneous troubles, was the exact type of the socalled lymphatic, as described by Sabouraud. She was a soft, delicate girl with a round, plump face, round limbs and a delicate white skin, which gave her the false appearance of being in blooming health.

The patient under consideration had both nipples affected with a heavily crusted impetiginous eczema covered with thick, yellow, brittle crusts. This was refractory to many forms of treatment usually successful in such eczemas until we finally painted it with equal parts of ichthyol and water, under which it cleared up admirably. There is always a tendency to recurrence, however, and occasionally it has been found advisable to use other remedies, such as nitrate of silver solution.

UNCOMPLICATED AND LIMITED STREPTODERMIA OF THE NIPPLE.

Quite distinct from the foregoing were the two following cases:

CASE III.—A woman, fifty-eight years of age, engaged in farm work, ran to overtake a horse that was running away and struck herself against the buggy wheels. She was bruised in many places, including the left nipple, which bled a little at the time. All the lesions cleared up in due time, excepting that on the nipple, which continued to ooze a clear or turbid serum. The surface from which this oozing took place was smooth, red and raw, and looked like a superficial burn. This condition had lasted over four months. There was no induration either in the nipple or in the breast. There was an enlarged, soft, lymphatic nodule on the thoracic wall of each axilla, probably the result of wounding her fingers in her rough work. She was in perfect general health.

CASE IV.—Almost the exact counterpart of Case III, except for longer duration and lack of an immediately foregoing traumatism, was that of a physician's wife, fifty years of age, who had inverted nipples, which had been itchy for years. On the left nipple there was a slight fissure in a bright red field and oozing a clear serum. This resembled streptococcic infection as seen in fissures behind the ears and at the corners of the mouth, and was so diagnosed. Treatment with ichthyol, boric acid soakings, and other measures adapted to this diagnosis, secured an apparent cure in both cases. This result was fortunate in the first because the patient was anxious lest her trouble might be cancer, and as a matter of fact, she ran danger of undergoing radical removal of the breast. In these last two cases, which differ decidedly from the first, the question of a commencing Paget's disease arises. We do not think this is the case, but it is always well to hold such an opinion in reserve.

323 GEARY STREET.

A Case of Rhinophyma and Its Cure*

By J. EASTMAN SHEEHAN, M.D., F.A.C.S.,
New York.

CASE.—The patient, a man aged fifty years, was referred to me by Dr. Cohen. His left arm and leg were paralyzed from an attack of apoplexy some five years past, and he had a hideous deformity of the nose, which so incapacitated him that it was impossible for him to obtain work. Since the repair of his nose, he has obtained a position receiving twenty-five dollars a week.

Rhinophyma is a disease which is the outgrowth of acne rosacea. This condition generally results in either a moderate or a severe nodulolobulated disfigurement of the nose. As a result of a persistent hyperemia, there occurs a hyperactivity of the sebaceous glands, a dilatation of the bloodvessels, ending in hypertrophy of the skin, due to new connective tissue formation, with the result that there is produced many follicular sinuses. The disease generally affects the lower anterolateral aspects of the nose, that is, the part of the nose which is supported with cartilage and which gradually blends

*Case presented before the Laryngological section of the New York Academy of Medicine, November 22, 1922.

FIG. 1.—Rhinophyma, before repair.

FIG 2.—Rhinophyma, after repair is complete.

itself with the normal skin, covering the bony framework. In some cases, there is present a true osteitis of the nasal bones and the nasal processes of the maxillæ, producing a wide upper nose, thereby adding to the deformity. This added deformity must be corrected by wedging the bones (1).

Operation.—The parts were cleansed with soap and water followed by alcohol and ether, until there was a decided glow. The mucous membrane of the nose was anesthetized with two per cent. cocaine muriate, and the external skin of the nose widely infiltrated with one half of one per cent. solution of novocaine. With a graft knife of the Thiersch order, the hypertrophied skin is completely shaved down to the sinus epithelium. Bleeding, which is likely to be smart, is generally controlled by applying pressure. As a result of the shaving process, which is carried to the basal line of the sinus epithelium, there results a raw area dotted here and there with bits of epithelium, which causes a quick epithelization of the parts. The exposed raw area is covered with ambrine gauze as used at Sidcup, England. As a rule, after ten days, epithelization is complete.

Tuberculosis Papulonecrotica with Serpiginous Lesions Resembling Tertiary Serpiginous Syphiloderm*

By MAX SCHEER, M.D.,

New York,

Attending Dermatologist and Syphilologist, Vanderbilt Clinic, College of Physicians and Surgeons, Columbia University, etc.

Grouping of lesions in papulonecrotic tuberculides sufficient to cause a marked resemblance to tertiary serpiginous lues has been rarely observed. Jadassohn (1) has observed in adults a variety of tuberculide characterized by the tendency to grouping but with the absence of necrosis. The case reported here was characterized by the presence of well developed necrotic lesions as well as grouping.

CASE.—F. H., female, forty years old, married fourteen years, occupation housewife, born in Hungary and ten years in this country, consulted us at the Mt. Sinai Skin Clinic on September 28, 1921. Her family history was negative.

She had had measles in childhood but none of the other exanthemata. She also suffered during childhood from frequent attacks of sore throat. Thirteen years ago, she had a miscarriage following a fall at four months of pregnancy; had had no other pregnancies. She had never had a serious illness. She had had occasional attacks of cough, but no other symptoms suggesting visceral tuberculosis.

Her present illness began twenty-five years ago, with pustules on the legs. These pustules dried into crusts which fell off in a few days leaving pitted scars. New lesions appeared more or less constantly since, affecting the lower extremities in their entire extent. The lesions on the hands and elbows first appeared five years ago. These never became pustules nor necrotic. Before coming to this country the patient was under treatment at the Allgemeine Krankenhaus in Vienna in the service of Prof. Ehrmann. She was told that her disease was tuberculide. She was treated with x rays. No antiluetic treatment was given.

On both lower extremities throughout their entire extent, but most marked on the buttocks, knees and ankles, were numerous circular and oval, flat or pitted scars from a pin head to a quarter of an inch in diameter. On the inner and outer sides of both ankles were numerous dry reddish brown pea-sized papules. The tops of some of these were

*From the Mt. Sinai Dispensary and the Vanderbilt Clinic.

necrotic. On the outer side of the left ankle these papules were arranged in a serpiginous configuration surrounding an area of pigmentation and scarring strongly suggesting tertiary lues. In fact, when

Fig. 1.—Lesions on knuckles of left hand.

first seen by colleagues at the clinic and at the Academy of Medicine, several were unwilling to make a differential diagnosis, while one unhesitatingly called it lues.

On the knuckles of the left hand were numerous violaceous dry and firm papules, the largest an eighth of an inch in diameter. Two similar lesions were present on the knuckles of the right hand on the index and ring fingers. These lesions were smooth and showed no scaling nor necrosis.

On the tip of the left elbow was a violaceous infiltrated plaque three quarters of an inch in diameter; one inch below the lesion was a firm subcutaneous nodule, irregular in outline and about the size of a marble; overlying skin was violaceous in color. The lesion was movable on the deeper parts. No subjective sensations were present in any of the lesions.

Between the angle of the jaw and the lobule of the left ear was a mass the size of a pigeon's egg. This was irregular in outline, movable, covered by normal skin, and somewhat firm. It had been present three or four years and gave rise to no trouble. Unfortunately the patient refused to have this excised. There was a moderate thyroid enlargement but no symptoms were present referable to thyroid disturbance. Physical examination of the internal organs was negative. On September 29, 1921, a physical and x ray examination of the lungs showed no evidence of active tuberculosis.

A routine urine examination was negative. A Wassermann test on admission at the Mt. Sinai Clinic was reported anticomplementary. On October 13th, a Wassermann test done at the Vanderbilt Clinic was anticomplementary.

A biopsy was made from lesions on the left foot and the left hand. The pathological report by Dr. D. L. Satenstein was as follows:

Low power. Throughout the entire cutis were foci of closely packed cells of various types. In places these foci had a tendency to be conglomerate, especially marked in the mid cutis. Throughout the entire cutis, especially marked in its upper portion, was a varying degree of inflammatory reaction. The vessels were dilated, some were filled with blood; the perivascular lymphatic spaces were dilated and a moderate number of cells were present about the vessels. The connective tissue throughout was edematous and in some places degenerated. The epidermis throughout was more or less uniformly thickened.

High power. The nodules were composed mainly of epithelioid, connective tissue and round cells. The protoplasm of the epithelioid cells was granular; the outline of the cell body was indistinct; an occasional mitotic figure was present. There was no distinct tubercle arrangement. The connective tissue fibres within and immediately around these nodules were fibrillated, broken and in some places granular. In the centre of one of these areas was a typical giant cell (chorioplaque type). The perivascular infiltration was predominantly round cell. Outlying this infiltration were irregularly scattered epithelioid cells. An occasional plasma cell was noted lying between the connective tissue bundles without any relation to the vessels or nodules.

The walls of the vessels in the subpapillary zone were thickened, due to edema. There was no hyperplasia. The endothelial cells were swollen and projected into the lumina. The lymphatics in this area were moderately dilated with the endothelial cells projecting. The vessels in the papillary bodies were markedly dilated and the endothelium swollen. The deep vessels were similarly thickened due to edema. There was some vacuolization within the vessel walls.

In the deeper tissue, where there was a large nodule, some newly formed bloodvessels were visible. At one edge of the tissue there was a marked degeneration of the connective tissue fibres; they were fragmented and granular. Broken down poly-

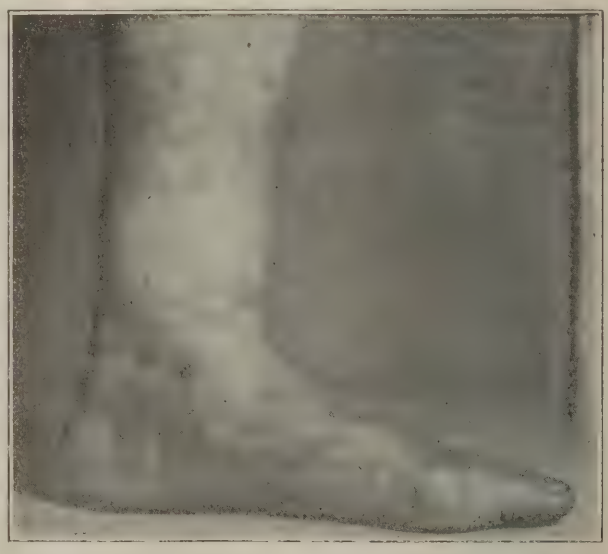

Fig. 2.—Lesions on ankle of left foot.

nuclear leucocytes were present (granular degeneration). This area was independent of the nodules. The epidermis presented acanthosis and marked parakeratosis. Tubercle bacilli were not found.

From the absence of hyperplasia of the vessel walls and absence of perivascular plasma cell infiltration syphilis can be excluded.

The presence of nodules with the epithelioid as

the characteristic cell, the presence of a giant cell within a nodule, thickening of vessel walls due to edema and not hyperplasia, the presence of newly formed vessels in the nodules and degeneration of connective tissue, all would point to a tuberculous process. Grouping the clinical with the pathological findings we concluded that we were dealing with a tuberculide which might be designated as a tuberculosis disseminata nodularis.

The lesion from the foot resembled the one just described, differing in that the nodule formation was deeper. The nodules were separated from each other by larger areas of degenerated connective tissue, which was a predominant feature in the slide. The character of the cells was similar to that described above. The inflammatory tissue reaction had a tendency to be more superficial and there were more degeneration and vacuolization of the cells of the vessel walls. Nowhere did we find hyperplastic vessels or perivascular plasma cells nor any of the usual findings found in syphilitic tissue.

The patient received arsphenamine injections intravenously, as follows: October 18, 1921, 0.3 grams; November 3, 1921, 0.3 grams, at which date the Wassermann test was negative with two antigens; November 10, 1921, 0.3 grams; November 17, 1921, 0.3 grams; November 29, 1921, 0.3 grams, and December 8, 1921, 0.3 grams.

After the second injection a slight improvement was noticed, especially in the lesions on the ankles which became flatter, though there were still some necrotic papules. Most of the improvement occurred on the right ankle. The nodules on the hands were slightly smaller but otherwise unchanged. There was no change in the elbow lesions.

At the completion of the six injections all lesions had disappeared from the hands and ankles and the right elbow; those on the left elbow were somewhat smaller. There was no change in the mass on the left side of the neck.

The patient returned for observation on March 7, 1922, stating that new lesions had been appearing for the past three weeks. At this time there were new nodules on the dorsal surface of the left hand and on both ankles, similar to the original ones and some even larger.

On March 8th a nodule was excised from the left hand and a guineapig inoculated by Dr. Hopkins. The animal was killed in six weeks. At the point of inoculation a nodule was found which on histological examination proved to be a foreign body tubercle; two nodules were found in the spleen which showed no evidence of tubercle structure. No evidence of tuberculosis was found. The patient received arsphenamine again.

While the nodules disappeared from the left hand, the outbreak of new ones during the period of salvarsan administration was striking. Three dark red elevated nodules one quarter inch in diameter appeared on the anterior surface of the lower third of the left leg. Two appeared on the left elbow and several on the left foot.

Status on May 4, 1922, was as follows: Dorsal surfaces of hands were free from lesions. There was a violaceous patch on the tip of the left elbow but no nodule. The tip of the left elbow showed two nodules. The mass on the left side of the neck was unchanged. There were about a half dozen new papules around both ankles. They were slightly elevated, a few discharged pus, but most of them had a yellowish white, dry, adherent crust. The recently healed lesions left violaceous macules, the older ones brown spots. On the left leg, just above the ankle, there was a raised, violaceous and tender nodule half an inch in diameter and indistinguishable from erythema induratum. Two similar nodules were situated nearby on the anterior surface of the left ankle.

On May 12th, Dr. Ornstein made the following tests: The Von Pirquet cutaneous reaction was positive. The patient reacted violently to one in two thousand milligrams of old tuberculin intracutaneously with both local and general phenomena; also to an autourine inoculation.

On September 15th the patient was examined by Dr. Ornstein, when she presented the following findings: Right lung, normal breath sounds; no adventitious sounds heard. Left lung, dullness anteriorly to the second rib and posteriorly to the fourth vertebral spine; bronchovesicular breathing anteriorly to the first rib. A few fine mucous râles were heard at end of respiration; the râles were not constant, and disappeared after coughing. There were diminished breath sounds to the fourth vertebral spine and bronchovesicular breathing between the fifth and eighth vertebral spines. Subcrepitant and coarse mucous râles were heard at the base; the râles were constant and increased by respiration.

X RAY REPORT.

Right lung.—The root shadows were exaggerated and extended out slightly into the parenchyma of the lung. There were many calcified areas (probably calcified tubercles) ranging from the size of a bean to a hazel nut. There was also peribronchial infiltration of the vertebral trunk.

Left lung.—The root shadows were exaggerated. There was infiltration of the vertebral trunk and trunks to the first and second interspaces; there was a calcified tubercle in the circle of the first rib.

Diagnosis.—Old healed root tuberculosis and peribronchial tuberculosis.

At the time of this examination there were many active lesions of the same character as described above on the hands and ankles.

SUMMARY.

The case described presents lesions of papulonecrotic tuberculide simulating a serpiginous syphilide.

Under antisyphilitic treatment some of the lesions retrogressed temporarily but reappeared in the midst of further antiluetic treatment (arsphenamine).

The histological picture and the laboratory tests corroborate the diagnosis of tuberculide.

There are cases of papulonecrotic tuberculide which so closely resemble syphilis that a clinical diagnosis is made with the utmost difficulty.

I wish to express my thanks to Dr. Fordyce for his courtesy in extending to me the privilege of using the laboratory at the Vanderbilt Clinic and to Dr. Andrews for the photographs.

The Choice of Operation in Gastric and Duodenal Ulcer*

By RAYMOND P. SULLIVAN, M.D., F.A.C.S.,
New York.

The management of gastric or duodenal ulcer cases should always include careful search for distant foci of infection, and when found treated appropriately, thus removing a probable etiological factor of the ulcer. Further, I believe it a wise practice for surgeons to request a competent medical treatment of these patients, especially in the early cases, because of the advantages, not only for the ulcer, but the patient in general. The principal determining factors which warrant surgery in these cases are: 1, acute perforation; 2, recurrent hemorrhage; 3, chronic, obstinate cases with or without obstruction; 4, persistent recurring pain which may indicate a localized peritonitis or penetrating ulcer. While this grouping may be considered a general plan, we frequently meet a problem of economics in these patients, which will mitigate against a comprehensive medical treatment, because of the time element involved, the inconveniences of diet schedule, and other conditions. This group should be offered surgery early because it is a more direct method of treatment, which, in a majority of cases, will greatly minimize the time element.

The choice of operation in the treatment of gastric and duodenal ulcer is still a debated procedure, controversy on this subject in surgical circles being hardly less animated now than it was twelve or fifteen years ago. At that time the subject of discussion was whether or not simple gastroenterostomy or a more radical procedure, such as excision or resection, was preferable. Opinion is still far from being unanimous, and the formulation of a routine procedure in ulcer of the upper digestive tract would seem to be out of the question, in view of the fact that the surgeon's further procedure must be governed by the findings at operation.

The individual operative methods in general use for ulcer of the stomach, as well as of the duodenum, may be divided principally into two groups: 1, those in which the ulcer is left to itself and simple gastroenterostomy with or without exclusion of the pylorus is done; 2, those which are directed against the ulcer as such, viz., excision or cauterization, partial resection of the stomach or duodenum, and reconstruction of the continuity of the digestive tract.

GASTRIC ULCER.

In the surgical treatment of gastric ulcer the customary methods may be briefly enumerated as follows: 1, excision alone; 2, excision plus gastroenterostomy; 3, resection of the ulcer bearing area; 4, jejunostomy for massive ulcer.

Briefly commenting on these various procedures, it may be stated that excision alone will find its most frequent use in ulcers of the cardiac end, or small ulcers along the anterior wall. Excision plus gastroenterostomy will find its most frequent use when the ulcer is situated distal to the Hartman line, principally in the pars pylorica, on either the anterior or posterior wall or lesser curve. Resection will find its most frequent use in multiple ulcers of the pylorus, or pars pylorica, or large callous ulcers of the pars media, or in any ulcer that has the slightest suspicion of malignancy. Sleeve resection is utilized in suitable cases, particularly in the presence of hour glass contraction situated in the pars media. Ulcer excision may be done with knife or cautery, or cautery destruction may be the method of excision. No matter where the ulcer is situated in the stomach, excision or destruction of the ulcer should be considered. Resection is indicated in ulcers of large size, or those having the slightest suspicion of malignancy. In acute perforating ulcers, practically the same technic is applicable as in chronic gastric ulcer, although the question of peritonitis must always be considered when the most appropriate procedure is being determined. The simpler the technic the more rapid the operative procedure in acute perforating ulcer, the better the prospects of a successful outcome.

The success of gastroenterostomy rests principally on mechanical rather than chemical grounds, as after its performance the peristaltic wave is lessened, with the result that by securing mechanical rest, physiological rest is secured at the same time, and the ulcer is given opportunity to heal. Hardt has recently pointed out that the pain of gastric or duodenal ulcer is primarily due to the peristalsis acting on an irritable focus, and that all medical measures by which gastric acidity is neutralized or suppressed also inhibit the gastric peristalsis and thus relieve the pain.

The effect of different operations for gastric ulcer upon the motor function of the stomach was recently discussed in the transactions of the Petrograd Medical Society, where Dehn pointed out that conditions following resection, according to Billroth II, are unphysiological, gastric atony being rendered worse than before operation. In resection, according to Billroth I, the physiological conditions may be restored. There was considerable discussion concerning the removal of the pylorus as being of greater importance than the removal of the ulcer. Following resection, according to Billroth II, the peristaltic wave could be shown to pass only along the greater curvature, because the annular muscle is a fanshaped arrangement in the lower gastric segments; so that in resection more fibres are divided on the lesser than on the greater curvature. Some adherents of gastroenterostomy assert that gastric ulcer is a general disease and therefore prone to return even after a so-called radical operation. Gastroenterostomy yields good immediate results and is less dangerous than resection, having a mortality of one half that of resection. The useful Polya operation is really a gastrojejunostomy following pylorectomy. Balfour's modification of the Polya operation is really an anterior gastroduodenostomy in continuity. This anterior operation seems to have found a wide acceptance, and has proved valuable in many of my cases.

Gastroenterostomy is advisedly added to cautery excision as well as to knife excision of gastric ulcer.

*Read before the Brooklyn Surgical Society, February 1, 1923.

Balfour's cautery excision or destruction of the ulcer may be applied in a large percentage of cases, and entails a minimum of operative risk. Both the opponents of gastroenterostomy and of resection are agreed in recommending cauterization after gastrostomy in suitable cases.

The adherents of resection affirm, in its favor and against gastroenterostomy alone, that after the latter the adhesions still persist, the stomach remains fixed, and the pain may continue. The postoperative course is simpler, after resection, and is less likely to be complicated by hemorrhage or perforation of the ulcer. The mortality of resection in the stage of hemorrhage is estimated by Finsterer as 6.2 per cent., and is expected to decrease still further if the patients come to operation sooner than is usually the case. Finsterer's employment of novocaine conduction anesthesia, instead of deep general anesthesia, is attracting considerable attention at the present time. It is also stated that recurrences are rather frequent after gastroenterostomy, but very rare after resection. Another objection, often raised against gastroenterostomy, is the possible onset of peptic ulcer in the jejunum—the cause of this grave complication being due to the pylorus, which must therefore be removed.

In Fedoroff's opinion gastroenterostomy, although yielding a lower mortality than the radical operative procedure, cannot be regarded as the operation of choice in the treatment of gastric ulcer, being indicated only in cases associated with obstruction; whereas, in all the remaining cases radical intervention is indicated.

Another Russian operator, Hesse, also defends resection, calling attention to the conservative views of the majority of both European and American surgeons. Hesse performs resection according to Billroth, in gastric ulcer, preferably Billroth I, considering the removal of the pylorus the most important point. He considers resection contraindicated in patients who are in bad general condition, or in ulcers situated near the esophagus. In the discussion of Hesse's recent address, Grekow opposed resection and defined the routine performance of this operation as an exaggerated procedure, pointing out that resection ignored the etiology of ulcer. He therefore advocates gastroenterostomy, to which he invariably adds pyloric exclusion. The only indication for resection, in Grekow's opinion, is found in those cases where there is reason to suspect malignant degeneration of the ulcer.

Hesse's opinion is supported by Oppel and Petroff. On the other hand, Kornen emphasized that although gastroenterostomy at first gives good results, up to ninety-five per cent., the permanent results are not so satisfactory. He stated that experience at autopsy or repeated operation showed that part of the recurrences were due to displacement of the gastroenterostomy opening, and this is especially apt to be the case with an open pylorus, viz., in ulcers of the gastric fundus. Gastroenterostomy is, therefore, more rational when the pylorus or duodenum is involved than in ulcer of the fundus, especially as in the former groups the ulcer can be protected against mechanical irritants by autoplastic exclusion methods. Kornen, therefore, prefers excision to gastroenterostomy, unless multiple ulcers or severe adhesions are present. The last named cases involve serious technical difficulties and the mortality is high, so that gastroenterostomy is preferable as it serves also to improve unfavorable conditions and the chemistry of the stomach contents.

Haberer, in Germany, points out the disposition to ulcer formation is removed by resection. Krause advises that resection should be restricted to ulcers of the gastric fundus and pyloric ulcer associated with chronic hemorrhage, or incipient perforation.

The operation of jejunostomy has not many advocates in this country as a surgical procedure in the treatment of gastric or duodenal ulcers. However, it will be useful in the presence of chronic hemorrhage, especially of the weeping type where total gastric rest is desired. Further, it may be found the procedure of choice in the presence of massive ulcer, especially of hourglass type, when more radical procedure is impracticable or too hazardous because of the poor general condition of the patient. I have used it on two occasions. In one it proved very satisfactory and permitted secondary resection with successful outcome. In the second case death resulted in two months after operation. The case was one of repeated hemorrhage, yet in spite of transfusions and careful search for bleeding points death resulted from a massive gastric hemorrhage.

We may then consider that the surgical treatment of gastric ulcer should consist in excision or cauterization of the ulcer with posterior gastroenterostomy in the majority of cases. It is in cases especially of the callous type that resection finds its chief adherents. But there are authentic observations proving that ulcer of the stomach may be successfully treated by means of simple gastroenterostomy. The pendulum must not be allowed to swing too far back, however, in the form of unconditional rejection of resection in the treatment of these patients. Recourse, fortunately, can always be had to gastroenterostomy in those cases where for some reason or other resection appears impracticable or difficult.

DUODENAL ULCER.

In the surgical treatment of duodenal ulcer as distinguished from gastric ulcer, the principal operative procedures are represented by 1, posterior gastroenterostomy alone, judiciously selected and performed; 2, cautery destruction plus gastroenterostomy; 3, excision of the duodenal ulcer alone; 4, excision with some form of pyloroplasty; 5, radical resection of the duodenum as advocated by Finsterer. The fact has recently been emphasized by Guerry and others that, according to the statistics from many sources, gastroenterostomy alone will bring relief in more than eighty per cent. of all cases of duodenal ulcer in which operation is performed, due to the fact that the stomach is put mechanically at rest and the ulcer is no longer irritated by peristaltic waves. Gastroenterostomy is undoubtedly not infallible in all cases of duodenal ulcer, but the vast majority of its failures have been explained by Moynihan as due to three, more or less avoidable, causes: 1, absence of an intrinsic lesion in the stomach or duodenum; 2, incomplete operation which leaves a diseased appendix or gallbladder to act as a focus for recurrent infection; 3, faulty technic. To this group C. H. Mayo adds gastrojejunal ulcers. Stating that gastroenterostomy when properly selected and carried

out has offered exceedingly good results in the treatment of duodenal ulcer. Judd believes it best to continue to use this method in most cases. He emphasizes that duodenal ulcers should not be excised unless the technical steps of the operation can be performed satisfactorily, which is possible only if the duodenum is mobile or easily mobilized.

Pyloric exclusion in any form in the presence of duodenal ulcer is rejected by most surgeons of today principally because it fails to prevent the contraction of the gastroenterostomy opening. Moreover, it has by no means been established that duodenal ulcers heal more readily after pyloric exclusion than after ordinary gastroenterostomy. Fedoroff emphasizes that the gastric acidity after pyloric exclusion is not diminished to the same extent as after simple gastroenterostomy, resulting in one of the conditions which favor the origin of jejunal ulcer. Sheeren reports that a large number of jejunal ulcers follow pyloric exclusion, and that this operation has been abandoned in the London Hospital. It would seem, therefore, that plication of the pylorus, with gastroenterostomy, possesses merely a palliative value. Resection of the duodenum in the presence of duodenal ulcer has become the operation of choice according to Haberer and Finsterer. The latter combines an extensive resection of the pylorus as a combination, arguing that the smaller the stomach remnant, the smaller will be its secreting surface, hence less prospect of the production of peptic ulcer of the jejunum.

Concerning the choice of operation in duodenal ulcer, it is evident, from a review of opinions, that gastroenterostomy is still holding its own as the safest and most desirable method of procedure. However, Judd points out that there are undoubtedly a group of cases in which it seems well to excise the ulcer in preference to performing gastroenterostomy. Although convinced that the excision of duodenal ulcer will never become a general practice, or take the place of gastroenterostomy, Judd recommends excision as particularly indicated if the entire ulcer can be excised and the duodenal lumen maintained, and if the entire operation can be more easily done than gastroenterostomy. Excision is also given the preference in ulcers of the type that bleed during an attack, or in ulcers associated with local pain but with inconsiderable symptoms of dyspepsia. Ulcer excision is better than gastroenterostomy if the gastric acids are not high, and especially if the patient has a tendency to neurasthenia. In all favorable cases for excision, the application of a pyloroplasty should be considered.

The selection of the proper operative procedure in ulcer of the stomach as well as of the duodenum, involves the necessity of a careful study of the causes back of the ulcer formation, together with their discovery and removal, in order to guard against recurrences and other complications for which the surgical intervention as such is not necessarily responsible. Not only expert technic, but also the scope of the operator's surgical horizon, if I may so express myself, will raise or lower his standard of cures, while at the same time guiding and governing the choice of operation in the treatment of gastric and duodenal ulcers.

270 Park Avenue.

Relative Brain Weights in Animals

By H. F. SLIFER, M.D.,
North Wales, Pa.

Report of observations made on the relative proportion of the brain weight to the body weight of certain animals:

	Body.	*Brain*	*Relation*
English sparrow, male	504 gr.	16 gr.	1/31
English sparrow, male	456 gr.	14 gr.	1/32
English sparrow, male	480 gr.	13½ gr.	1/35
English sparrow, female	480 gr.	14 gr.	1/34
English sparrow, female	442 gr.	12 gr.	1/35
Field sparrow, male	480 gr.	13½ gr.	1/35
Field sparrow, female	401 gr.	14 gr.	1/28
Wood pewee, female	408 gr.	7½ gr.	1/54
Canary, male	360 gr.	8½ gr.	1/42
Canary, female	180 gr.	7½ gr.	1/24
Robin, male	1164 gr.	24½ gr.	1/47
Robin, female	1502 gr.	23 gr.	1/65
Quail, male	3360 gr.	16 gr.	1/210
Quail, female	3360 gr.	17 gr.	1/197
Pheasant		40 gr.	
Crow, female	7720 gr.	135 gr.	1/57
Owl, small horn, male	3360 gr.	85 gr.	1/39
Owl, small horn, female	2400 gr.	74 gr.	1/33
Prairie chicken	19 oz.	38 gr.	1/240
Prairie chicken	21 oz.	34 gr.	1/296
Hen, young	72 oz.	54 gr.	1/640
Cock, young	56 oz.	60 gr.	1/448
Duck, male	6 lb.	70 gr.	1/600
Duck, female	5¼ lb.	100 gr.	1/367
Goose, male	8½ lb.	180 gr.	1/375
Mouse, male	282 gr.	5½ gr.	1/51
Mouse, female	247 gr.	6 gr.	1/41
Field mouse, female	540 gr.	10 gr.	1/54
Mole, male	3 oz.	16 gr.	1/90
Rat, male	11 oz.	34 gr.	1/155
Rat, female	7¼ oz.	29 gr.	1/120
Cat, male	8 lb.	464 gr.	1/121
Wild rabbitt, female	2 lb.	104 gr.	1/134
Tame rabbit, female	5 lb.	154 gr.	1/227
Squirrel, grey	no weight	94 gr.	
Squirrel, red	no weight	60 gr.	
Opossum, male	8½ lb.	88 gr.	1/675
Skunk, male	4¾ lb.	170 gr.	1/207
Porcupine, female	11 lb.	250 gr.	1/308
Pig, male	175 lb.	4½ oz.	1/622
Bull	1340 lb.	17 oz.	1/1261
Ox	940 lb.	12 oz.	1/1253
Cow	750 lb.	12½ oz.	1/960
Horse	1160 lb.	21 oz.	1/884
Frog	4½ oz.	4 gr.	1/540
Trout	1 lb.	10½ gr.	1/666
Spanish mackerel	3¼ lb.	18 gr.	1/1458
Mackerel	4 lb.	28 oz.	1/1000
Flounder	3½ lb.	22 gr.	1/1114
House fly	¼ gr.		
Head of fly	1/20 gr.

Historical Medicine

Hydrophobia: Four Hundred Years Ago

By HON. WILLIAM RENWICK RIDDELL, LL. D., F. R. Hist. Soc., Etc.,
Toronto, Canada.

The celebrated and most learned physician, mathematician, philosopher, poet and Latinist, Girolama Fracastoro (or Fracostorio, Lat. Hieronymus Fracastorius) of Verona is now known only from being the inventor of the word syphilis which first saw the light in his *Syphilidis sive Morbi Gallici libri tres,* published at Verona, 1530—a Latin hexameter poem in three books. But he wrote many and published some other Latin works, some in verse, others in prose. One of his prose works is *De Contagionibus et Contagiosis Morbis et eorum curatione* (*Contagions, and Contagious Diseases and Their Treatment*). This is in three books of which the first deals with contagions generally, the second with contagious diseases and the third with treatment. It is proposed in this paper to give some account of his views concerning rabies, interesting as it is both from a historic point of view and the elegance of the language.

Rabies is first named in Lib. II, cap. x, p. 170 (1): he says that according to Galen this disease exists *per se* (2) only in the dog; and that according to Aristotle, every animal bitten by a mad dog becomes rabid except man—and they are nearly right. In his first book, he had divided contagions into three classes, 1, those by direct contact only; 2, those by direct contact and by *fomes,* i. e., substances like clothes, etc., which not attacked by the disease themselves act as a nidus for *seminaria* of disease, and 3, those by direct contact, by *fomes* and by action at a distance. Rabies is of the first class: not every contact, however, is effective but only contagion introduced by the blood itself by the tooth and froth of the rabid dog, the skin being broken and blood drawn. The contagion is sluggish, rarely does it appear before twenty days, generally after thirty, often not for four or six months, sometimes a year, and sometimes after five years. Fracastoro had himself seen a boy who died of it, in whom the disease manifested itself after eight months. In the meantime there is no fever or other ill, but when the contagion at length reaches the heart, "it afflicts the man with unspeakable torture, the heart and precordia are lancinated (vellicantur), the sick man can neither stand nor be still, but torn this way and that, like a madman, he tears his body with his hands, he has a raging thirst, but the worst is that he dreads water and all liquids so much that he would sooner die than drink or be brought to the water—then, too, they bite others, frothing and with wild eyes, and at length worn out they miserably breathe out their life." It is said (3) that if anyone formerly bitten by a mad dog lie under a sorb apple tree, he will again become mad. This, *"si modo verum est"*—if it is true (4), (as the author wisely says) is due to styptic and melancholic vapors exhaling from the tree, carried to the man and being heated within him producing *seminaria* of the disease on account of the diathesis (dispositio) left behind by the previous rabies.

Fracastoro held the universally accepted theory of four humors in the body on the condition and due proportion (crasis, temperamentum—mixture, combination) of which health so much depended. Sanguis (blood), phlegma or pituita (phlegm or rheum) chole or cholera (yellow bile) and melancholia (black bile): and considered that rabies was due to the last named. He gives as reasons for this conclusion that the rabid act like melancholics (5) and the dog is by nature very melancholic. Moreover the contagion has analogy only to phlegm and melancholia: the phlegm is much more abundant than the melancholia (6) and if the contagion had its seat in the phlegm the disease could not be so long in making its appearance.

Other animals than man become rabid and die when bitten because of the wild nature (feritas) in them like in dogs so that in case of contagion they must become rabid by analogy: but the nature of man is far different, far removed from this wild nature and analogy, "whence it happens that not all who are bitten even become rabid but many by reason of their natural constitution (temperatura) either do not contract the contagion at all or if they do, survive." Probably that is what Aristotle meant.

It is difficult to give the reason why the dogs themselves and those who have been bitten by them have such a fear of water. No credence is to be given to Aetius and many other who say that *hidrophoui* fear water because they imagine they can see puppies (*catulos*) in it—some just beginning to fear water being asked, said they did not see anything of the kind. Nor does it arise from any affection (indisposition) of stomach or tongue as in some diseases—for there is thirst and so far as the tongue is concerned, it longs for and seeks what is wet—the defect is in the imagination (phantasia). Perhaps the imagination awakens the memory of some past events which are wont to inspire fear—when they see the froth around the mouth and feel their heart melting within them (liquescunt), the imagination conjures up some fluid drowning them, whence the fear when they touch liquids or hear liquids offered to them (7).

TREATMENT.

In Book III, cap. ix, pp. 251, sqq., we have the treatment fully explained. This is, like carbuncle (called by the Greeks, anthrax) and gangrene but even more so, a disease for which if it be not attended at the very beginning, there is no cure; accordingly its symptoms and immediate treatment should be known to all. "But in rabies," says Fracastoro with some humor, "the priests to whom those bitten are immediately brought act better than the doctors for they, exercising the religion of operators and the office and instruments of medical men, themselves burn the spot" (8). Everyone should know that if it be possible, the bitten place should be burned, i.e., cauterized with the actual cautery. It would be better,

however, first to scarify the wound and cup it with a large cupping glass, then burn so deeply as to reach the *seminaria*—the cautery should be glowing hot iron, silver or gold. If the actual cautery is considered by anyone too severe (*nimis impium*) you may use caustic medicaments. Where you cauterize take care that a crust is formed using Brassica leaves anointed with butter; and also apply evocant and drying (9) unguents. If you fear that the disease has sunk its roots deeper, do not burn the place; that would drive the poison further in; scarify and use an evocant and drying plaster such as this: (10)

Galbani .. Serapini .. Opoponacis	āā	℥ss
Euphorbii		ʒiii
Iridis ..... Xiridis ..... Aristolochiae Gentianæ ...	āā	ʒiij
Nitri ..... Sulfuris	āā	ʒii
Ceræ	q. s.	..

Evacuants are always to be exhibited—the best are the *hieras,* that of *Archigenes* and that called *diacolocynthidos,* also hellebore than which there is nothing better in this disease if administered in goat's milk whey—Epithymum is also effective and "in general, everything which purges the melancholic humor."

The contagion is checked, too, by medicines which have a particular antipathy; all mention the ash of burned rivercrabs, gentianroot, some mix thus with it. Alyssum is favorably spoken of—the name is derived from its making a man to be without madness (11)—the Arabs call it *alguasce.*

"Nor would those in our judgment err who would exhibit rubia minor either contused or with a little vinegar as a draught, because it is effective against serpents—neither would those who would give syderitis because that is an admirable desiccant. Aetius praises a recipe of a certain old man, oxylapathum used externally or internally—that is not the oxylapathum which is called acetosa (for that is Oxalis) but another which has the pointed leaves and seed among the Lapatha."

NOTES.

1. My copy of Fracastoro is the edition of his works, Geneva, Typis Jacobi Stoer, 1637—it is from this edition that all the quotations are made in this paper.

2. *Per se,* in itself—here it means original, not produced by contagion, etc., but the expression has many shades of meaning in mediaeval philosophy.

3. *Ferunt*—they say—this expression is used by Fracastoro in repeating what is said by others either of his own or former time, without vouching for its accuracy—in most cases, doubt is connotated.

4. He adds *"quod fama quadam circumfertur"*—or is circulated by a certain report. *Seminaria* are the seedplots or nurseries of contagion, formed by the evaporation of insensibly minute particles which occurs in every putrefaction—every contagion contains a putrefaction but not vice versa.

5. Melancholia until the latter part of the eighteenth century includes all kinds of nervous affections from simple "crankiness" through hysteria to actual melancholia. It was long believed to be due to an excess in black bile; about the middle of the eighteenth century the theory made its way that it was due to viscidity or gluiness of the blood.

6. Both phlegm and melancholia are mythical and nonexistent humors.

7. Fracastoro according to his usual custom goes off into a long discussion of the phantasia and its works—how the sick often from seeing small figures on the walls imagine they see wolves and dogs and cry out and demand their removal, etc., etc., but I spare my readers. He does not give any explanation of the fear felt by the dogs.

8. *"Quod in Rabie Sacerdotes melius instituere quam medici, ad quos statim deducuntur, qui demorsi sunt, quos curantium religione tum medicorum officio et instrumentis utentes, urunt enim et ipsi locum."* It will be remembered that until the Council of Tours in 1163 forbade the shedding of blood by monk or priest, the practice of surgery was largely in the hands of the clergy. In Fracastoro's time barbers were the chief surgeons, but in the case of dogbite the priests were permitted to apply the actual cautery and did so without or acting for barber or medical man. The idea of the passage quoted is that the priests acting with the conscientiousness (*religio*) of operators made proper and immediate use of the proper instrument.

9. *"Unguenta quae simul evocent et exiccent"*—unguents which at the same time draw out the poison and dry up the humor.

10. See next note for a glossary of all the plants, etc.

11. Alyssum from the Greek, "a" without, and "lussos" (Latinized lyssus)—madness. What we call alyssum or madwort is a genus of the mustard family, Cruciferæ; we have two species on this continent—*a,* maritimum, the white flowered sweet alyssum of our gardens, and *b,* saxatile, rock alyssum, with yellow flowers—both are importations from Europe.

Archigenes, a noted physician of old who made a wonderful *hiera.*

Aristolochia—birthwort—so called from its supposed value in childbirth; we have three species on this continent, a. Serpentaria Virginia Snakeroot, b. Sipho, pipevine or Dutchman's pipe; and c. tomentosa, the common snakeroot.

Brassica is here B. oleracea, the cabbage—of course turnips, mustard, wild mustard, etc., are all Brassicas.

Cera wax, here bees' wax.

Diacolocynthidos—a *hiera* of which a main ingredient was colocynth, for the same purpose and with the same effect as Pil, Comp. Col.

Epithymum—Cuscuta Epithymum or Dodder, growing on thyme—thymus vulgaris.

Euphorbium—we now call euphorbia, spurge—this is probably the E. platyphylla naturalized on the Continent from Europe.

Galbanum is officinal.

Gentiana is officinal.

Hellebore is the black species H. niger, Christmas rose.

Hiera—a laxative or purgative medicine—we sometimes have *hiera picra* still: many physicians had their own *hiera,* some of them very famous like that of Archigenes.

Iris—a family of plants has this name—the Iridaceæ: The genus iris has many species, iris, flag, flower-de-luce, etc. This iris is probably the Iris Florentina whose rootstock furnished orris root.

Lapathum is Sorrel, Rumex acetosella—the whose genus of rumex were lapatha.

Nitri—the ordinary nitre or saltpetre but in those days very generally impure—we now expect reasonably pure potassium nitrate.

Opoponax or Lacrymæ panaceæ, an imported gum, yellow externally and white internally, obtained by incision of the trunk of the tree Panax which grew in Macedonia, Boeotia and other parts of Greece.

Oxalis—Oxalis acetosella, woodsorrel.

Oxylapathum—Rumex acetosella.

Rubia—Madder. We have only the Rubia tinctoria, common or dyers' madder.

Serapinum—sometimes called Sagapinum—a bitter red to yellowish gum with a garlic-like odor used as an antispasmodic and emmenagogue. It was obtained from the Ferula Persica. Ammoniacum, another medicinal gum—came from the Ferula Ammonifera in Tripoli.

Sulphur, the native sulphur was always preferred.

Syderites or Heraclea was apparently a Madder, Rubia, or possibly a Betonica.

Thus—Frankincense.

It may be of interest to find what Fracastoro teaches of the treatment of Rabies in dogs. In his poetical work *Alcon, sive de Cura Canum Venaticorum*—Alcon, or concerning the Care of Hunting Dogs—the old hunter Alcon discourses to the young Acastus, concerning hunting dogs, the choice, breeding, training and diseases of them—and the treatment of these diseases. I give the treatment of

rabies here in a translation practically literal: "When struck by a venomous serpent . . . he knows himself how to find a healing grass and cure himself without assistance—but when he experiences rabid bites, mix forthwith Idaean pitch with leaves of rue and sour wine and apply the medicament to the injured part. . . . But what particularly calls for the care of the skilled mind is when inflamed with rabies, he attacks now these, now those, and turning against the master himself, he inflicts the incurable wound. Therefore first of all confine him with a strong chain; then pound to powder with a heavy stone the roots of the field rose, mix with dark linseed and add water from a living spring. This administered as a drink, it is said the dog recovers his original senses and the rabies disappears. Some grind wild figs and old lard; others direct to soften ivy leaves in boiling water until only a third remains and to feed the rabid animal with the leaves and the water at daybreak. Nothing however is so advantageous as at the very beginning to cut out the seeds of the disease with the steel—for where the tongue in its most remote part joins the palate and throat, a wound giving worm is to be found of the color of native gold, which drives the wild hounds (molossos) to madness and fills their mouth with venom, which if any one can cut away (resecare), he will remove the cause of such a terrible disease and the stimulus or madness." Even here the author shows his caution in respect to the operation of medicines—"they say"—"tradunt."

A Sixteenth Century Latin Poem on the Diseases of Nurslings: "Pædotrophia," by Scévole de Sainte-Marthe.—Dr. Charles Greene Cumston (*Annals of Medical History,* December, 1922). Scévole de Sainte-Marthe, member of an illustrious family of Poitou, was born in 1536. He became a star in the legal firmament of France, held the office of surveyor general of finance of Poitou, of president of the paymasters of France, and later of Mayor of Loudun, a position which gained for him the title of "father of his native city."

Copies of this poem are exceedingly rare. It is dedicated to Henry III of France. In this dedication the author states the subject of his poem to be "the manner of nourishing infants at the breast, and of protecting these young and tender plants against the infinity of storms and tempests that menace them, and often cause them to perish at birth."

The poem opens with an invocation to the Muses and Apollo, then comes a song about the exploits of the King, then an exhortation to the author's wife, in which he counsels her to omit no care in protecting her offspring and emphasizes the necessity of mothers nursing their children themselves. The subject of pregnancy is next discussed, and a few precepts given, among them, a warning against too tight clothing, control of the passions and avoidance of sadness and fear, alternation of work with rest, no dancing, careful selection of foods, and control of pathological appetites. After a discussion of birthmarks as the results of maternal imaginings, he counsels women approaching labor to invoke the protection of the Goddess Lucina, three times in a loud voice, then to choose the position most comfortable for being delivered.

The second book describes what should be done when the child is born, stating that formerly the umbilicus retained the two sexes united in such fashion that they formed a single one, although in reality there were two, but after this bond of union was ruptured these bodies became free. If an infant cries weakly after birth, and shows evidence of little vigor, it is a sign that the father is in poor health, or that the child suffered *in utero* from malnutrition, or that it sustained a considerable traumatism at birth. The child should be kept very warm if it be winter, but only temperate if it be summer. The infant's body should be sprinkled with wine. If it is very feeble, it should be warmed by blowing warm breath over it. This is far superior to every other remedy for fortifying an infant, especially if the blower holds in his mouth a piece of cinnamon bark. Washing and cleansing, composing the limbs into their proper shape, and purging with honey are emphasized. The wet nurse and the child's diet are discussed throughout the rest of this book.

The third book deals with the diseases to which very young infants are subject. These are inflammation from the cutting of the umbilical cord, *frænum linguæ,* and various inflammations, tumors and ulcers of the throat and mouth, for the most part due, according to the author, to bad or defective milk. The pain in teething, he maintains, comes from the teeth endeavoring to open up a passage by means of an acrid humor, which serves them as an augur, the boring causing the pain. He prescribes rubbing the gums with a hare's brain or honey. If this fails, the head should be moistened with water and rose water, each tepid, and then covered with a woollen cap. The treatment of constipation, diarrhea, colic, worms, vomiting, insomnia, nightmare and cough, *prolapsus recti,* eczema, smallpox, measles, and epilepsy, are described. Scévole considers insomnia, nightmare and cough as having an identical cause. He states that, when children have taken more milk than their stomach can digest, the milk transforms itself into crudities from which a thick vapor rises. This vapor imparts to their imagination during sleep false mental pictures, and, since the brain by nature is cold, these vapors, entering into its substance, become condensed there as clouds do in the air, and like them fall in rain, hence irritating the throat of the child with their acrid moisture, producing a cough which ultimately settles upon the chest. Smallpox, he believes, is caused by Nature's attempts to expel impurities of the blood. He recommends the drinking of much cold water, and an infusion of honey for both infant and nurse. If the disease proves obstinate, he wisely advises doing nothing, and warns against the custom of the day of employing such violent remedies, with intent to cause the poison to come forth, that these strong drugs cause ulcers of the throat, obstructing respiration. He states that this ill timed method of treating smallpox caused the death of his two children. According to certain of the author's contemporaries, he was the first to advocate bloodletting at the onset of smallpox.

In his discussion of epilepsy, Scévole suggests two causes for this malady: It may result from a sticky pituita overfilling the brain and preventing distribution of the animal spirits, so that the nerves suffer from violent jerks in their endeavor to eliminate that which is injurious to them; or epilepsy may be due to a vapor derived from a cold poison, distributed over the body and finally insensibly reaching the brain, which undertakes to defend itself against the invasion, but the thinner the vapor, the more easily will it penetrate the cerebral substance. The author reminds us that several of the world's great men were epileptics, among them Hercules, Cæsar, and Mohammed.

MEDICAL JOURNAL PROGRESS

The year 1924 marked the beginning of a new epoch in the history of this journal. With the first issue of the New Year the name became the *Medical Journal and Record*. This change of name was the result of many years of development. Gradually the field of our contributors and readers has widened until the journal has come to represent the most progressive in medicine of all parts of the United States. Our policy has been to avoid the ordinary static groove into which it is so easy to settle. We have also gone to Europe and secured the best writers we could find there.

So it has come to pass that we have outgrown any purely local functions. Long before the change in name we had become national in circulation and international in scope. Today we feel that we stand as the most progressive medical journal on this continent. So much for the name.

In the course of our progress, we have recently added several new features. Our department of Historical Medicine will deal with the very foundations of the entire glorious achievements of the men who have made medicine what it is today. We shall include from time to time in this department the historical record of many men who have contributed to our present day knowledge of medicine. We owe these men a deep debt of gratitude and to ourselves we owe the acquirement of a knowledge of their lives and work.

The best of our innovations we come to finally. Beginning with the issue of February 6, 1924, each and every issue of the *Medical Journal and Record* will contain a supplement, which will cover a definite branch of medicine with the newest findings in this field. We shall present in each supplement a symposium which will be of value to the general practitioner and also serve as an authentic source of information for the specialist in the particular field represented. The remainder of the articles will be in the nature of original communications covering the entire field of medicine. The supplement will be a very attractive feature of our journal and will be arranged in a manner to facilitate its being bound separately and will be printed on special tinted paper.

Our aim is to create a journal which will be indispensable to every progressive physician. We have never lacked courage to make a change which we believe spelled progress. Our desire is to cooperate with our readers, to be of real service. So we feel another milestone has been passed.

Those of our many friends who have followed our growth and marked our progress will be sure to agree with us. We hope to make many new friends and so broaden our field of usefulness. Each one of our readers can aid by telling some colleague of our plans, aims and achievements. The more physicians we reach, the better will be our service. This in turn will be of benefit to all our readers, yourself included.

May this be the most prosperous year to readers of the *Medical Journal and Record*. May we go hand in hand to do all we can to further the progress of medicine.

THE ART OF LIVING LONG.

It was said once by a keen observer of a somewhat cynical manner of expression, probably a Frenchman, that for one to hope for long life one must take care to choose one's parents wisely. Whether long life is to be desired depends largely on circumstances; health and temperament are leading factors, but, at any rate, everyone is interested in the length of life.

Mr. Alexander Graham Bell some time before his death attempted, if not to solve, at least to come into closer touch with the problem of longevity. In order to do this he studied the records of an ordinary family through several generations. It may be said that while his figures were published privately they are more or less common property and are extremely intriguing. Altogether, 8,797 persons were included in his tables. The crude average of life was 34.61. It should be mentioned that those whose age at death could not be ascertained were included. Again, thirty-five per cent. died before reaching the age of twenty. The first year of life is the most dangerous period. According to the figures collected by Bell the point is brought out that adolescence is also a critical time, the mortality increasing steadily year by year from fifteen to twenty-three years of age. Often, up to the age of thirty-five, the decline is considerable. The curve mounts somewhat during the years thirty-five, thirty-six and thirty-seven. No support, however, is given to the theory that fifty is a dangerous age. The number of deaths remains fairly constant until extreme old age. Somewhat more than seven persons in every hundred lived to eighty or longer.

Some interesting and curious results are given by an analysis of deaths according to sex. Under five, there were more deaths among males. From five to twenty deaths among females numbered the most. From twenty to twenty-five a larger number of males died. From twenty-five to forty-five, the child-

bearing period, the reverse was the case. From that time on the male mortality was always higher. These figures will not be accepted universally, although it is generally agreed that females live longer than males.

The figures, though tentative as to the individual expectation of life, are, in a high degree, interesting. They show that, apart from accident, longevity is very largely a question of heredity. If the parents are both longlived the chances are that the children will be also longlived. Moreover, if one parent dies prematurely and the other lives to a great age, the figures of Bell suggest that, on the whole, the longevity of the male parent counts for more than that of the female. Another point which should interest eugenists greatly is that fertility means long life, that is to say, fathers and mothers who had the most children were the longest lived. In the case of the male this fact expresses no particular significance, but in the case of the female it is quite the reverse. Mothers who died under forty had on the average three to four children. Those who died between forty and sixty had 6.2 children, between sixty and eighty 6.6 children, while those who lived to be eighty or older averaged 7.2 children.

Figures which relate to the only child present a curious problem. The only child, speaking generally, does not live as long as members of a large family, and the larger the family the longer the expectation of life. This does not appear to be difficult of explanation; probably or presumably it is because a large family may be taken as a fair indication of healthy and virile parents. Yet an analysis of the year of marriage in which children were born yields singular and, in a way, disconcerting results.

These figures seem to prove that children born in the first ten years of marriage are distinctly longer lived than those born from ten to eighteen years after marriage. This is easy to understand but the disconcerting part comes after, as the curve goes suddenly up instead of down, so that children born eighteen and nineteen years after marriage are as longlived as the average of the whole. This is mysterious and requires more evidence than Bell's set of figures before it can be accepted as conclusive.

The statistics commented on give one to ponder. One man said that figures never lie while another man, a hard headed Scotchman, gave it as his opinion that statistics, like sausages, depended a good deal upon the old woman who made them. The truth lies probably in the happy mean. Statistics are not always reliable, they can be cooked and can be arranged to fit in with a person's preconceived views almost unconsciously. On the other hand, carefully collected and collated statistics are of the utmost value, but to be conclusive they must proceed from various independent sources, deal with similar conditions, with numerous cases over a considerable length of time. In the instance of statistics on longevity sufficient evidence has been already forthcoming to show that heredity is a potent factor in longevity, by many considered the most potent. With regard to some of the other points raised by the data brought together by Bell they are all suggestive, some more than others, but as said before, much more evidence is needed to clinch them.

BETTER EYESIGHT FOR CHILDREN

Quiet persistence has characterized the effort to give our children better eyesight than the present or past generations possessed. Fifty years of struggle have produced results. Better light and better seats in the schools have done much toward reducing eye trouble, but, when we come to deal with the individual child, certain obstacles are still apparent which as yet prevent full realization of the ideal. Among these obstacles may be mentioned unskilled treatment by nonmedical practitioners, the patronage of such practitioners by many medical men, a prejudice against the use of drops, and an erroneous conception of the use of glasses. We are tempted to intersperse with our remarks on this subject a few of the terse, pithy sentences used by Edwin Harrison in his paper on Eye Health and Safety, published in the *Western Medical Times* for September, 1923. In the interest of absolute truth it should be noted that a certain inaccuracy is always inherent in an epigrammatic style. Thus his statement, "If the child's eyes are properly cared for they will be good in old age," is true, provided they do not become injured by accident or disease, mishaps that no care in childhood can guard against.

"Why trust the child's eyesight to anyone but a properly trained specialist? Between the optician and the oculist there is the same difference as between the druggist and the doctor. A sensible person when ill does not ask the druggist to prescribe. The druggist who asserts that he can do this better than the doctor proves himself unreliable." True, yet druggists do prescribe and will continue to do so because many of their customers demand it, and so will opticians and optometrists continue to maltreat the eyes for the same reason. But that is no reason why a doctor should advise his patients to seek relief from druggists or optometrists when they have troubles which he is not prepared to treat. If he sends his eye cases to an optometrist, he ought not to complain if the oculist recommends such of his patients as need attention to their internal organs to go to a druggist. In both cases the patient might

get the right glasses or medicine and be told how to use them correctly. Or, in both cases, relief might come in spite of a wrong glass or a wrong drug, for all the organs of the body, including the eye, are wonderfully tolerant and Nature tries hard to rectify mistakes. The great tolerance of human eyes is shown by the fact that most people who have to wear glasses remain comfortable when the frames have gradually become bent so as to tilt spherical lenses until they create an artificial astigmatism, or change the axis of a cylindrical correction five, ten, or fifteen degrees. When a person has been suffering from eyestrain an incomplete relief often gives a grateful sense of comfort, so a wrong glass may relieve the symptoms for a time.

Often it is the desire to save the doctor's fee that impels the patient to consult the druggist or the optometrist. Does he succeed? This is questionable. Proof is lacking, but it seems to be the general impression among eye doctors that the following statement is very nearly correct: " 'Come to me and save the oculist's fee' advertises the optician who wants to make an illegitimate profit. The person who responds pays more for his glasses in the end than the combined charges of a reputable oculist and the optician."

" 'We use no drops' is the claim of certain 'eyesight specialists' who, though they have not passed a medical examination, often style themselves doctors or oculists. Were they to carry this deception further and sign M. D. to a prescription or use drops, they would be liable to arrest and punishment. Attempting to make a virtue of the necessity of not using drops, they inform you that belladonna, atropine, and other eye drops are harmful. Drops are not always used by oculists, and when they are it is because rest is essential for the strained eye, and because correct glasses cannot be fitted otherwise." If the eye were simply a camera any mechanic accustomed to the handling of lenses could fit eyes perfectly well. But the eye is not simply a camera. It contains a muscle which is apt to assume a state of spasmodic contraction as the result of strain and thus conceal the true refractive condition. Drops are used to relieve this spasmodic contraction by placing this muscle in a state of absolute rest, and are efficient whenever they succeed in doing this. Sometimes they fail, usually because the drug employed was too weak to allay the spasm. The presence or absence of such a spasmodic contraction cannot be determined without a proper examination, but when the oculist believes drops are not needed he does not use them.

Rest glasses are referred to by patients and optometrists as though they were something which could be given and worn to advantage without the necessity of accurate fitting. There is no such thing. "The only correct rest glass is one that has been prescribed after a careful measurement of each eye for its individual defects."

A much smaller proportionate number of sore eyes are to be found in the schools today than was the case a generation ago, and many more of the children wear glasses. This shows the improvement in the children's eyes which has taken place. A very important next step is to be sure that each child has the right glasses. More parents than formerly are willing to have their children wear glasses when needed, and they exhibit an increasing willingness to submit their children to the annoying but necessary methods of a real examination. One way in which the doctor can help along this good work of securing better eyes for the children is to advise his patients to avoid the optometrist and optician, who have only mechanics' skill with lenses, and to consult a medical eye specialist when he has not the training to do the work himself.

DISTRIBUTION OF MALARIA ACCORDING TO CLIMATE AND SEASON

If the distribution of paludism over the surface of the globe be examined it will be found that nearly all countries present more or less considerable malarial areas. But malaria is far from assuming everywhere the same aspect and the same gravity, between the mild paroxysms observed at the present time in Camargue, for example, and the severe paludism of tropical regions there is such a difference that one has the impression of having to do with two distinct diseases. This difference is due to the greater intensity of infections in the tropical zone, perhaps dependent upon the debilitating effect of the climate, but above all upon the strain—the race—of the parasite.

At the present time it is generally admitted that malarial regions can be divided into three categories, namely, tropical, subtropical and temperate regions. The tropical zone is characterized by a distinct prevalence of the Plasmodium precox, India furnishing a typical example. The temperate zone, as the central part of France, is characterized by the almost exclusive presence of the Plasmodium vivax, cases of precox infection observed almost always being imported. Between these two regions exists an intermediary zone—the South of France, Italy, Macedonia, Algeria—where both parasites are encountered in practically the same proportions but at different seasons of the year.

Therefore, climate manifestly influences the type of hematozoon met with and generally speaking it can be said that the Plasmodium precox is the para-

site of warm, the vivax that of temperate climates. The explanation of these facts is as follows:

The temperature may in the first place act directly on the parasite at the time of sex reproduction in the mosquito. Janczo's experiments on this subject have shown that the zygotes do not reach maturity at a temperature of 16° C. or below. These experiments very clearly explain why the precox can only exceptionally develop in France and why in subtropical countries it is in summer only that the initial paroxysm of the first invasion occurs. On the contrary, in tropical regions where the temperature is more even and warmer the time during which the anopheles can develop an infection is much longer.

But these data can only explain the geographical distribution of cases of first invasion and recurrences due to reinfections. Senevet believes that the latter exist but are infinitely less numerous than some observers maintain. He has already combatted this thesis in relation to the pathogenesis of relapses recurring in a short time and W. M. James has also pointed out the small part played by the anopheles in the genesis of relapse. In the regions about the Panama Canal this writer observed that the increase of the epidemic of malaria at the commencement of the malarial season was out of all proportion to the number of anopheles. A certain time is required for the mosquitos to bite, to become infected and thus transmit the disease. The number of cases of malaria increase rapidly directly after the rainy season; likewise in the neighborhood of cities where the number of mosquitos does not markedly increase. Although the rain may make the mosquito enter dwellings, thus increasing the chances of reinfection or infection, the increase in the number of the mosquitos in houses is not sufficient in relation to the number of cases of malaria. Besides, at the end of the wet season, the epidemics drop rapidly at the same time the rain ceases and much more rapidly than the number of mosquitos does. These data show that a close relationship exists between the exposure to cold on the one hand, and the increase of the malarial epidemic on the other, also between the cessation of the exposures and the decline of the epidemic.

These facts as well as the spontaneous arrest of malarial paroxysms at the end of certain seasons, show that the season and climate act on the parasite contained within the body of the host. It is the play of these two actions which explains, according to Senevet, the appearance of the majority of relapses occurring after a considerable lapse of time. In subtropical regions, such as Macedonia, a person is infected during summer by both parasites, the precox and vivax. The latter ceases its manifestations after a few paroxysms, while the precox will continue its cycle. Consequence: relapse follows relapse. Now this same person goes to France about the middle of October with the result that there some paroxysms will develop due to the precox, after which the vivax comes into play. Another subject infected in the same circumstances remains at Salonica, where he continues paroxysms due to the precox until the end of December and only in February will his relapses develop due to the vivax. In the first example the patient has a change of climate; from a subtropical zone he goes to a temperate one, quite unpropitious for proliferation of the precox, but where the cool season, favorable for the vitality of the vivax, comes on much earlier than in Macedonia. His organism has become refractory to the præcox and if it had only been infected by it, the patient would have appeared to be completely cured.

Such data are not pure speculation; they have been noted by many observers, particularly Marchonx who has pointed out paroxysms from Falciparum are rare in France because for reasons yet unknown, malignant tertian appears to be recovered from spontaneously in that country. On the contrary, in the latter case, the patient remains in the same country which from its climate renders his organism propitious for the precox and he must await the end of the season of the year favorable for this parasite, for the paroxysms to stop. The change thus produced will then permit the vivax to commence its cycle.

To sum up, it can be said that there are two parasites, one of summer, the other winter. Warm countries belong to the first, the temperate to the latter, so that their alternation is completely dependent upon seasons. Individual factors can alone cause the paroxysms to occur at other times than the season properly belonging to each.

PROGRESS OF WOMEN IN OCCUPATIONS

A report has recently been issued by the Women's Bureau of the Department of Labor interpreting the census statistics of women in gainful occupations. The chief feature of this report is the great change shown in the type of occupations that women have been adopting for the past ten years. There has been a decided increase in the number of women entering the clerical and allied occupations, in teaching and in nursing, and a marked decline in the number working in the home and in personal service occupations. A great change is shown also in the manufacturing and mechanical industries. Increases of more than ten thousand women were evident in the semiskilled operatives in food, iron and steel, in the clothing industries, and in silk and knitting mills; among forewomen and overseers in manufacturing plants; in electrical supply, shoe, and cigar and tobacco factories; and among laboring women in cotton mills. Women workers in automobile factories

showed an increase of 1,408 per cent., and in the iron and steel industry of 145.4 per cent. Women in public service occupations had increased 60.6 per cent. In several of the occupations included in the study the percentage of increase for women was more than one hundred points higher than that of men in the same occupations. Men cooks, for instance, increased 12,853, and general servants 11,292, while the decline in the number of women in these occupations runs into the hundreds of thousands. Men actors and showmen decreased in this decade more than 1,400, while women increased more than 1,200. Men authors, editors and reporters decreased by several hundreds, and women in the same professions increased by nearly 2,500.

Interesting and important health problems are involved in these occupational changes. It is usually conceded that industrial conditions are "man made," and it will be worth watching to see whether or not women will be willing to accept them. Also, will women's health withstand as well as men's the health hazards present in so many of our modern industries?

NEW YORK TO STUDY INDUSTRIAL HEALTH HAZARDS

The New York State Department of Labor is to make an intensive study of industrial diseases and accidents, based upon data affecting 1,225,000 workers in more than seventy thousand industrial plants. This announcement was made at the annual Safety Congress of the National Safety Council at Buffalo by Dr. Leland E. Cofer, director of the division of public hygiene of the New York State Department of Labor.

The plan is to study conditions as they now are, so that results of improvements may be properly appraised in the future. In doing the work, every opportunity will be embraced of teaching the worker how to work well and economically from a physiological and psychological point of view, as well as how to look after his personal safety and health. Doctor Cofer stated that the industrial hygiene division of New York State examines annually approximately five hundred sets of plans of devices for removing dust and fumes from workrooms. It is proposed to analyze the results of this experience. The intention is also to make a special effort to enlist the interest of the medical profession in the State in recording and reporting, not only specific industrial diseases, but other diseases that may be associated with industry. It is hoped that the cooperation of the organized public health institutions, and of the business and labor interests may also be enlisted in the effort to make this study of significance and value to the problem of industrial and public hygiene.

INTERNATIONAL MENTAL HYGIENE

Plans are being made for an international congress on mental hygiene and related subjects to be held in this country probably in 1925, so the National Committee for Mental Hygiene announces in one of its publications. These plans are under the direction of an organizing committee of which Mr. Clifford W. Beers, secretary of the National Committee, is general secretary. The idea of an international congress and of the founding of an international committee for mental hygiene has been under discussion for some time, but impetus was recently added through a visit made by Mr. Beers to France, Belgium and England, all of which countries have organized national mental hygiene societies. While in Paris, Mr. Beers conferred with delegates from ten countries, and as a result of this meeting general plans for an international congress were agreed upon. The organizing committee which is directing the project then consisted of representatives from twenty-one nations. Delegates from Italy, Spain, Hungary, Denmark and Norway promised to take steps toward founding national bodies in their respective countries so as to take part in the conference. Since the meeting, representatives from Germany, Sweden and Japan have joined the organizing committee and will work toward establishing societies in those countries.

Mr. Beers was elected to honorary membership in the British National Council for Mental Hygiene, he addressed a large public meeting under its auspices in London, and later broadcasted a talk in its interests. He spoke also at the annual banquet of the British Medicopsychological Association and to special groups at Oxford and Cambridge Universities.

AN UNUSUAL TYPHOID CARRIER

The latest report of the Newark Health Department contains the portrait and story of a rather unusual type of male typhoid carrier. Tony Labella is about forty years of age, is unmarried, a Sicilian by birth, and presents the picture of rugged health. He came to the United States more than twenty years ago, but sixteen years ago returned to Italy on a visit. He denied any typhoid history, but stated that when he was fourteen he was ill for two weeks with "stomach trouble and malaria." His condition was discovered in 1921 by the State, and he was considered the cause of an epidemic resulting in seventy-two cases, with three deaths. He was registered by the State, given instructions; and apparently followed them for some time. He consulted a laboratory and apparently was given a favorable report, so he went to work on a farm that marketed milk in Newark. At first he did little of the milking, but later took part in this work, with the result that there was a second epidemic of typhoid of thirty-five cases and six deaths. When the dairy was investigated, following the epidemic, Labella gave a false name. The stool test was taken from dry stool and proved insufficient. All the tests were negative, but a State agent recognized Tony from the previous epidemic, and a fresh stool proved him still a carrier. He was committed to the City Hospital, photographed and finger printed, and ultimately released under agreement of specified occupation. His condition is possibly of twenty-five years' standing. Perhaps he is an intermittent carrier—a single negative test, in his case, means little or nothing. The case illustrates the urgent need for stricter registration laws and vaccination regulations for milkmen and food handlers of all types.

News Items.

Military Order of Foreign Wars Reelection.—At the annual meeting of the Military Order of Foreign Wars, Dr. William Seaman Bainbridge was reelected commander and Dr. James Howard Huddleston, surgeon of the New York Commandery.

Fourth Harvey Lecture.—Dr. David Marine, director of laboratories, Montefiore Hospital, New York City, will deliver the fourth Harvey Society lecture at the New York Academy of Medicine on Saturday evening, January 19, 1924. His subject will be Etiology and Prevention of Simple Goitre..

Alvarenga Prize Announcement.—The College of Physicians of Philadelphia announces that the next award of the Alvarenga Prize will be made on July 15, 1924. This essay must be received by the secretary of the college on or before May 1, 1924. The prize for 1923 was awarded to Dr. Edward P. Heller, Kansas City, Mo., for his essay entitled Treatise on Echinococcus Disease.

World Trip Offered to Physician.—A four year trip around the world on a private yacht is offered to a physician who is interested in medical research. He would be expected to render the few services necessary in a medical capacity on the trip in return for his tour and all expenses, and could have unrestricted writing liberty. Interested physicians are to communicate with Mr. Barry Buchanan, Players' Club, 16 Gramercy Park, New York; telephone, Gramercy 6116.

American Congress on Internal Medicine Sessions.—The eighth annual clinical session of the American Congress on Internal Medicine will be held in St. Louis, Mo., beginning Monday, February 18, 1924. Practitioners and laboratory workers interested in the progress of scientific, clinical and research medicine are invited to take advantage of the opportunities afforded by this session. Address inquiries to the secretary-general, 1002 North Dearborn Street, Chicago.

Endocrine Clinic to Be Conducted.—An endocrine clinic for the study and correction of endocrine disturbances, in children particularly, will be conducted by Dr. A. Weil, endocrinologist; Dr. J. Gutman, internist; Dr. H. R. Litchfield, pediatrist; Dr. E. Giddings, laryngologist; Dr. B. B. Berkowitz, dermatologist; Dr. S. Kleinberg, orthopedist, and Dr. J. Pensak, dentist, on Tuesday and Saturday afternoons from three to six at the Brooklyn Diagnostic Institute Building.

Personal.—Miss Jane Pine has been appointed managing editor of *Hygeia.*

Dr. Louisa Helena Hart, an American physician who is in charge of the Mary Lott Lyles Hospital at Chittur, Madras, India, has been awarded the Kaiser-i-Hind medal of the first class by the British Government.

Dr. Mabel E. Elliott, for four years medical director of the Near East Relief in Turkey, Armenia and Greece, has recently returned to America. For many months Dr. Elliott was in charge of a rescue home for Armenian girls released from imprisonment in Turkish harems. Dr. Elliott is now on a speaking tour for the Near East Relief.

International Clinic of Plastic Surgery.—St. Andrew's Hospital, London, England, will be enlarged for the teaching and practice of plastic surgery. It is estimated that about $120,000 will be required to carry on this work. The staff includes the names of H. D. Gillies and T. Pomfret Kilner, of Great Britain; J. Eastman Sheehan, of New York; Ferris N. Smith, of Grand Rapids, Mich., and Professor Lemaitre, of France.

American Psychoanalytical Round Table.—A round table of the American Psychoanalytical Association was held in the Fraternities Club Building, New York, on Friday, December 28th. Members and guests from various parts of the country took part in the discussion of the subject of the evening, the development of the concept ego, the part the ego plays in the individual and social adaptations of the human being, and some of the problems the ego presents in psychopathology.

Post-Graduate Medical School and Hospital Lecture Schedules.—The New York Post-Graduate Medical School and Hospital announces the lecture schedule for the month of February: February 1st, recent advances in diagnosis and treatment of diseases of the heart, by Dr. Robert H. Halsey, February 8th, the symptoms and treatment of injuries to skull and vertebræ, by Dr. Charles A. Elsberg. February 15th, laboratory aids in the diagnosis and treatment of syphilis, by Dr. Ward J. MacNeal, and February 29th, cleft palate, by Dr. Harold S. Vaughan.

Larger Journal of Röntgenology.—*The American Journal of Röntgenology and Radium Therapy,* the official organ of the American Röntgen Ray Society and the American Radium Society, will appear in enlarged form in 1924, the increased pages being given to additional illustrations, abstracts and more original articles. Dr. A. C. Christie, formerly Colonel in charge of röntgenology in the United States Army during the war, will be the editor. Dr. James T. Case, Dr. H. K. Pancoast and Dr. W. Duane will be the associate editors with a large collaborating staff of the leading röntgenologists.

Rockefeller Gifts for Medical Research.—Carrying out pledges previously made, $1,000,000 has been appropriated to the medical school of the University of Chicago, $1,000,000 to the medical school of the University of Toronto, and $225,000 to the medical school of the University of Iowa. In addition, $500,000 has been appropriated for endowment of the medical school of the University of Alberta, Canada.

A gift of £50,000 has been made to Edinburgh University by the trustees of New York for fuller equipment of the university on its medical side. The Edinburgh Medical School is one of the most famous in the world. The gift will be used for the erection of chemical and research laboratories in association with the Royal Infirmary and also for completion of the endowment of a professorship of surgery on a full time basis.

The Dean of the Faculty of the Welsh National School of Medicine, at Cardiff, announces that the trustees of the Rockefeller Foundation had notified him of their intention to make a donation of £14,000 to the institution to be devoted to the building of new laboratories and clinical facilities.

Foreign Correspondence.

LONDON LETTER.

(*From our own correspondent.*)

London, *November 20, 1923.*

MEDICAL TREATMENT UNDER THE NATIONAL INSURANCE ACT.

What has been known as the panel crisis, that is, the dispute between medical men acting as practitioners under the British National Insurance Act and the Ministry of Health and the Associated Societies, has passed. At one time it seemed as if this form of medical practice was about to end. The disagreement was concerning money and the Associated Societies. The situation was somewhat complicated, largely owing to the fact that these societies appeared to be disposed or even anxious to dominate and dictate to the panel practitioners. The settlement is in the nature of a compromise between these practitioners and the Ministry of Health while the societies assert that the doctors have won and protest against the decision of the conference to accept the terms offered by the Ministry. However, a special court of inquiry is to be set up by the Minister of Health as soon as possible, which will be instructed to report on the capitation fee to be paid. Whether this decision is satisfactory to the medical men concerned remains to be proved. The following are the proposals authorized by the Minister of Health and accepted by the Insurance Medical Practitioners:

1. The Minister accepts the following formula: "Medical benefit is, with sickness, disablement, and maternity benefits, one of the primary benefits under the National health insurance acts. Other benefits are additional and contingent upon the foregoing being first provided. The question of what is the proper amount of remuneration to be paid to the doctors, is one to be determined on its merits by the Government after due inquiry and after negotiation with the representatives of the profession.

2. An impartial Royal Commission will be appointed to investigate and report on the whole system established under the national health insurance acts, including medical benefit and the remuneration of the practitioners.

3. Provided the insurance acts committeee nominate an actuary of suitable standing, the Government actuary is prepared to meet him in professional consultation with a view to satisfying him that all relevant considerations have been taken into account in arriving at his conclusion as to the maximum which can be charged to insurance funds from January 1st.

4. As regards England and Wales, during the next year a sum of £250,000 will be provided for the mileage fund and to meet other points raised with regard to the rural practitioners by the deputation which recently saw representatives of the Ministry of Health on the subject; the Scottish mileage to be discussed as heretofore with the Scottish Board of Health.

5. As regards the arrangements for remuneration from January 1st, the Minister authorizes the following alternative offers: a, A capitation fee of eight shillings and sixpence to be paid for five years from January 1st, provided that if the Royal Commission referred to above during the currency of that period suggests any material alteration of conditions of service, the profession shall be free to reopen the question of remuneration; or b, a special court of inquiry will be set up by the Minister as soon as possible and instructed to report on the capitation fee to be paid from January 1st. The contract will be made on the basis of the fee recommended by the court of inquiry, the Government undertaking to go to Parliament for the necessary legislative sanction, and the profession undertaking to accept the recommendation. The court of inquiry will be asked to report as soon as possible, hearing any evidence tendered on behalf of the Ministry, the profession, the approved societies or other interested parties.

DEATH OF A GREAT SURGEON AND SANITARIAN.

Mr. Thomas Pridgin Teale, F.R.S., F.R.C.S., who died on November 13th, was one of the surgeons who maintained or rather enhanced the great reputation of the Leeds School of Medicine. To the general public he was known chiefly for his work in domestic sanitation, and especially for the improvement of house fires. He was born in 1831 and was the eldest son of Thomas Pridgin Teale, a surgeon in Leeds, who described and employed a method of amputation which is still associated with his name. He was educated at Oxford University where he was fourth in mathematics in 1852. He then became a medical student at King's College, London. After taking the diploma of M.R.C.S. he spent six months in visiting the medical schools of Europe. He obtained the degree of M.B. Oxford in 1856 and settled in Leeds. He then took the F.R.C.S., England, and lived to be the Senior Fellow of the Royal College of Surgeons. He became lecturer on surgery in the Leeds Medical School. In 1864 he succeeded his father as surgeon to the Leeds Infirmary. In 1876 he was nominated a Crown Member of the General Medical Council, and in 1888 he was elected F.R.S. In 1904 he received the compliment of an honorary D.S.C. from Leeds University.

Teale was primarily a teacher and a surgeon; secondarily, he was an apostle of domestic sanitation at a time when the public gave little thought to drains, ventilation or atmosphere. As a surgeon he collaborated with Sir Clifford Allbutt, then a physician on the staff of the Leeds General Infirmary, to revolutionize the treatment of the condition known as scrofulous neck, when as yet the infective nature of tubercle was unknown. It was formerly the practice to treat enlarged glands of the neck in children by poulticing, painting with iodine, or using other local remedies, with the result that matter collected and ugly scars were left. Clifford Allbutt advocated and Teale practised the operative removal of these glands as soon as it was obvious that simpler means were failing to give relief. The idea was new, but it soon met with general approval, for the surgical scar proved to be less unsightly than that produced by natural processes. He invented a means of extracting soft cataract and invented an operation for the relief of symblepharon. He was a skillful surgeon and in advance of his time. Teale was a great sanitarian and a pioneer of many of the methods by which British sanitation has become world famed.

LATIN AMERICA LETTER

(*From our own correspondent*)

BALBOA HEIGHTS, C. Z., *December 21, 1923.*

MEMORIAL TO THE FRENCH CANAL EMPLOYEES WHO DIED AT PANAMA.

During the time that the French Company was attempting the digging of a canal across the Isthmus of Panama, 1881-1889, the mortality from yellow fever, malaria and other diseases was terrific. The total number of deaths is placed at 22,189 and the annual death rate at 240 a thousand of population. These figures refer to the employees of the French Company. It seemed to the French citizens resident in Panama, and their friends in the Republic and the Canal Zone, that some memorial should be erected to these men who gave their lives in attempting the gigantic enterprise of the construction of an interoceanic canal, an effort which would have been crowned with success had the sanitary knowledge of man equalled his engineering knowledge at the time. As an example of the extent to which this ignorance hampered the project, a story is told of the Sister Directress of the really good, but unscreened hospital, which the French built. This estimable lady was very fond of flowers and at her solicitation members of her order in many parts of the world sent her various seeds and bulbs. These she planted, but soon discovered that unless they were to be destroyed by ants, some means of protecting them must be devised. The good Sister accomplished this by having constructed concrete shallow dishes of appropriate size and in these she placed water and the potted plants. Here was an ideal breeding place for the Aëdes stegomyia, the vector of yellow fever, and since the hospital was unscreened and was constantly treating the disease, if a nonimmune patient entered the hospital he was pretty sure to contract *fiebre amarilla* no matter for what cause he was admitted. While the accuracy of this story cannot be vouched for, it shows the way in which yellow fever marched unobstructed up and down the Isthmus until Gorgas and his coworkers came armed with the immortal discoveries of Reed.

Largely through the efforts of M. de Simonen, formerly the French *Charge d'Affaires*, the cooperation of the Panamanian government was secured, the old Chiriqui prison was largely razed and the plot of ground formerly known as Las Bovedas was transformed into the Plaza Frances. This was the site of the fortification which was erected when the city of Panama was transferred from the place where it was destroyed by the pirate Morgan. It is related that it cost so much to construct that the King of Spain thought he should be able to see it from the windows of his palace. In the old casemates of this fort were placed a series of plaques on which is recorded the essential history of the canal project from its inception in the sixteenth century to the present time and in front of a beautiful colonnade, statues were raised to certain of the more prominent French engineers. This forms a background for a pyramid surmounted by the gallic cock, a memorial to those gallant sons of France who were the pioneers of the work completed by the United States.

On December 2, 1923, the French Cruiser *Jeanne d'Arc*, with the Special French Envoy Le Comte de Bourdoncle de Saint Salvy aboard, arrived at Cristobal-Colon, and on the fourth he dedicated the memorial in the presence of the officials of the Republic of Panama and the Canal Zone and a large gathering of the pueblo. The ceremonies opened with the open air mass at which Chaplain Le Petit of the *Jeanne d'Arc* officiated using the vestments and altar service of the golden altar of the chapel erected in Paris on the site where Louis XVI and Marie Antoinette are buried. Following the religious ceremonies President Porras and Comte de Saint Salvy made addresses.

The entire incident was made a great fiesta by the city of Panama and there were official receptions, official dinners and balls, while for the *gente* there was a holiday with firecrackers and many forms of amusement.

RESEARCH WORKER VISITS THE ISTHMUS.

Dr. Patrick A. Buxton, of the London School of Tropical Medicine, arrived at Cristobal-Colon on December 1, 1923, on the *Athenic*, and sailed the following day for Samoa via New Zealand. He will inaugurate preventive measures against filariasis in Samoa and will be assisted by Mr. G. W. Hopkins, an entomologist, who accompanied him. Dr. Buxton was met at Quarantine by Colonel H. C. Fisher, M. C., U. S. A., the chief health officer of the Canal Zone, and by Dr. D. P. Curry, the assistant chief health officer. The party inspected the antimalaria work which is being carried on by the Health Department of the Panama Canal and visited various points of sanitary interest.

While Dr. Buxton's expedition is financed from the Milner Research Fund, which is intended to be used for the promotion of scientific research and not to subsidize or replace local efforts in sanitation, it will in this instance be used to stimulate effort to control disease conditions in the Samoa group which are now being administered by New Zealand under a mandate from Germany. Health conditions are reported to be very bad and are causing considerable anxiety on the part of the New Zealand government. The 1918 influenza epidemic killed almost a third of the population, dysentery is epidemic and tuberculosis is said to be spreading; filariasis and ankylostomiasis are sufficiently prevalent to complicate the local labor market. The mission will study these questions and will remain for two years in Samoa for the purpose. The personnel of the party will probably be considerably augmented by undergraduates from the local medical schools.

IDENTIFICATION OF CANAL ZONE TOP MINNOWS.

The Health Department of the Panama Canal has been conducting in the office of Dr. J. L. Byrd, City Health Officer of Cristobal-Colon, experiments in the propagation of mosquito larvæ destroying top minnows. Eight of these were sent to Dr. Barton A. Bean, Assistant Curator of Fishes, United States National Museum, and he has identified them as Poecilia sphenops, Cuvier and Valenciennes. These are well recognized devourers of mosquito larvæ and are one of the most variable and abundant of its family which ranges from Mexico to the Panama Canal Zone. Dr. Buxton took a liberal supply of this species with him for transplantation in Samoa.

Book Reviews

RADIOLOGY

Chronic Intestinal Stasis (Lane's Disease). A Radiological Study by ALFRED C. JORDAN, M.D. (Camb.), M.R.C.P. (Lond.) London: Henry Frowde and Hodder and Stoughton, 1923.

There is romance in medicine which appeals to the medical man and also to the layman. Medicine, while it has lost, to a very large extent, its mystery, has gained in romance to the layman. No branch of medicine typifies this romance more than radiology, and together with medical research these have filled the gap left by the dispelling or waning of the mystery. As far as medical research is concerned, doctors themselves admit freely that they are endeavoring to peer through a maze of which they are but on the outskirts. The greatest feats of exploration in this comparatively undiscovered field have been done in tropical regions and especially in Darkest Africa. The fastnesses of certain insect borne devastating diseases have been penetrated and the maladies themselves robbed of some of their terrors. Not all the triumphs of modern medicine, however, have been won in tropical lands; there have been wonder and romance in medicine in civilized countries. Radiology is the most striking example of a discovery at home, which has in reality opened up new fields and has advanced immensely the progress of medical science and the treatment of disease. By its aid diagnosis in some directions has been revolutionized and medical men may now gaze into the inmost recesses of the human body and regard them as the battleground of minute organisms, some of which are warring against and some defending the life of unconscious man.

Dr. Jordan in this book deals with radiology as applied to the interpretation of the intestinal problem and shows how successful the method has been in elucidating many of its obscure features. Indeed, it may be said without straining a point that lacking the aid of radiology our knowledge of intestinal conditions would be imperfect, almost elementary, instead of wide and accurate as is the case today. Dr. Jordan has largely devoted his inborn skill in this science, trained by experience, and his time on the clearing up of many of the moot points of intestinal stasis and has here recorded the results of the knowledge thus accumulated. Sir Arbuthnot Lane was the first to draw attention to chronic intestinal stasis and its probable and possible consequences and in a foreword to the book points out its great value to the medical profession, since the x ray shows by its pictures intestinal facts far more graphically than any written exposition. The book abounds in such pictured expositions. There is not space to make a detailed review of the work and therefore attention will be concentrated on certain of its most arresting features. Chapter IV should be studied closely as it discusses the method of examination employed by the author, the composition of the opaque meal used by him and his mode of administering it. He defends his methods against his critics and further states that his long experience has led him to the conclusion that the whole alimentary tract should be investigated in each case of chronic intestinal stasis.

In other chapters Lane's kinks and all parts of the intestines involved in and affected by chronic intestinal stasis are described with meticulous precision by words and pictures. One chapter is devoted to a consideration of colitis of the large intestine, a frequent accompaniment of stasis, while the succeeding chapter shows how far x ray investigations of cases of stasis determine the etiology and pathology of diverticulitis in the large intestine. It may be said that all the observations of the author have convinced him that diverticulitis is a consequence of colitis. The duodenum and duodenal ulcer in stasis are given a chapter for their description distinguished by some remarkable pictures. Gastric ulcer is dealt with in a like manner in the next chapter and therein Dr. Jordan delivers himself of a decided expression of opinion with regard to the relationship between chronic gastric ulcers and cancer.

It is his opinion that a good many chronic ulcers become cancerous. This is a vexed question and one around which much controversy has raged. According to the author radiography proves absolutely that many gastric ulcers become cancerous and radiographs are shown in support of the statement. A very intriguing chapter is that which is concerned with glycosuria in chronic intestinal stasis and cases are quoted and pictures of them shown taken from a paper by Dr. N. Mutch which appeared in *Practitioner,* May, 1915, which go to prove that there is a definite relationship between glycosuria and chronic intestinal stasis.

Several pages of the book discuss treatment of stasis including the operative procedures introduced by Sir Arbuthnot Lane. A chapter is given over to the relation between stasis and the prevention of cancer. Many authorities hold that civilization and especially civilized diet tend to produce or arouse cancer into activity and that consequently in the prevention of cancer careful diet and mode of living generally are important factors. Dr. Jordan takes the view that, in the first instance, chronic intestinal stasis by poisoning the body in every tissue and organ so lowers its resisting powers that it becomes strongly susceptible to the occurrence and development of malignant processes. Moreover, it is universally allowed that long continued irritation may initiate cancerous change in the predisposed.

Chronic catarrh of the large intestine is an extremely frequent condition in stasis and when long continued, although there may be no definite ulceration, there is always a certain amount of erosion of the mucous membrane. In fact, the conditions are such as to favor all changes of a malignant nature. Marked lowered resistance brought about by prolonged stasis, and advanced chronic irritation of the large intestine induced by a long standing colitis the effect of chronic stasis. Diverticulitis, too, may lead to cancer, and Dr. Jordan is of the opinion that there is always danger of cancer arising in the large intestine where bands and sharp angulations have formed and this danger is enhanced by peristaltic efforts to overcome the obstruction caused by bands and kinks. The author shows that when stasis has lasted for a long period that it produces numerous

means of chronic irritation in the large intestine favorable to the production of malignant disease. And lastly, as said before, Dr. Jordan supports the view that gastric ulcer may appear on the site of a chronic ulcer, that is to say, as far as can be judged by radiological examination.

According to the author, cancer may be brought about in other regions of the body by chronic irritation which in turn may be caused by long continued stasis. If these hypotheses be correct, and the evidence in support of them, in whole or part, appears to be increasing, then the prevention of cancer largely lies in paying close attention to the laws of health and especially so with regard to diet. At the end of the chapter on cancer Dr. Jordan has outlined methods of treatment, mainly by the means of suitable diet and by avoiding constipation, which should tend to prevent the occurrence of cancer.

The book is fascinating in a high degree and describes the romance of radiology as applied to the problem of intestinal stasis, in a way which simplifies and clarifies the subject greatly. Of course, there are many who think that chronic intestinal stasis and its effects have been exaggerated. However, there is no evading the fact that diseases of the alimentary tract are more in evidence than ever before and that ill health affecting perhaps one or other of all the organs of the body supervenes when the gastrointestinal machinery is not working smoothly. Indeed, pronounced stress throughout the book is laid on the point that in disease there is an essential unity, if one organ is in distress, the entire system is more or less involved. The part cannot suffer without prejudicially affecting the whole. Dr. Jordan has done a great service by demonstrating by pen and picture in a masterly fashion the mechanical changes produced by stasis as well as its bad influence on the general health. The volume proves up to the hilt the diagnostic value of radiology set forth by one who knows his subject from A to Z. The volume is a work of art in addition to being full of information. The printing is excellent and the x ray pictures which explain the text on almost every page are reproduced amazingly well.

OPHTHALMOLOGY

Traité d'ophthalmologie. Par le Dr. Poulard. Paris: Masson et Cie, Editeurs, 1923.

This is a work of somewhat uneven merit, the surgery of ophthalmology being given by far greater prominence than that bestowed upon its medical side. The entire work bears the unmistakable imprint of the author's personal experience, and insofar sustains his claim of its purely clinical character. The book is purged of all that is not of immediate value to the practising eye man, such as burdensome historical data, supposititious theorizing and controversial points that encumber and often pad unnecessarily an otherwise useful textbook. Of pathology just enough is entered into that will serve to elucidate the clinical picture. The American reader will be especially favorably impressed by the treatment of the subject of syphilis in its wide ramifications as it affects all the structures of the eye. Thus syphilis of the conjunctiva that is usually passed over, or barely mentioned in many a textbook, is given twelve pages out of the total of 153 devoted to the subject of conjunctival affections. Of the other subjects that are treated most thoroughly we may mention especially that of traumatism of the globe and orbit, glaucoma, and neurology of the eye. The surgery of the lids, to which especial impetus was given by the late war, is given the prominence that it justly deserves.

We were looking in vain, both in the index (which, by the way, is far from complete), and in the subject matter of the book, for even a mention of amaurotic family idiocy, a condition which, though rare, is nevertheless of sufficient importance to be alluded to in a treatise on ophthalmology. In the etiology of iritis the author fails to give due weight to the subject of focal infection. The American ophthalmologists were the first, we believe, to call attention to this subject; and while it may still be considered by some as *sub judice,* enough clinical material has accumulated by now to lay a firm scientific foundation for focal infection as an undoubted etiological factor in iritis.

The French reading ophthalmologist will find this work refreshing in its clarity of style and for the seemingly secure hold the author has on his subject.

CONSTIPATION

Habitual Constipation. By Ismar Boas, M.D. Translated by Thomas L. Stedman, M.D. New York: Funk & Wagnalls Co., 1923.

The present book on habitual constipation, coming as it does from the most eminent specialist on gastroenterology in Europe, deserves minute attention from every medical practitioner. Each page contains something useful for his future use.

Regarding the relation between constipation and neurasthenia, Boas is of the opinion that the latter condition is produced by the former. He expresses himself as follows: "While psychic excitement may exert a powerful influence on bowel activity, not only in a retarding but also in an accelerating sense (anxiety diarrhea), it would be going too far to say that every subject of constipation was first a neurasthenic or should be so treated. The reverse is often the case; the subject of chronic constipation who lives, as it were, with his bowel troubles and who sees no improvement in spite of many drugs and modes of treatment, falls gradually into a state of nervous unrest, becomes unduly concerned about his bowels, eats and sleeps badly, and in consequence gradually becomes a neurasthenic or hypochondriac. Among neurasthenics, on the other hand, habitual constipation may be nothing more than one of the many symptoms of which they are wont to complain; and even if the constipation is remedied, the neurasthenia is by no means cured but merely passes into another phase.

Boas exhorts the patient suffering from habitual constipation to follow the twelve golden rules: "1. Accustom yourself to go to the toilet every day in the early morning. 2. Do not protract your visit to the toilet beyond ten minutes; a longer stay is a sign that your bowels are not in good order. 3. Eat your meals at, or as near, the same hour every day as possible and eat them slowly. 4. Imitate the countryman in your choice of diet. Avoid large quantities of meat, fine confections and puddings. Let your diet consist chiefly of rye or whole wheat

bread, fats, fruit, vegetables and salads. 5. Spend at least a half hour or a whole hour every day, in fair weather or foul, in open air exercise. 6. Do not allow yourself or your children to fall into the laxative habit. The longer the abuse of cathartics has continued, the more difficult will be the cure of the constipation. 7. When you are forced to take a cathartic, select the simplest and the least harmful. 8. Reject all laxatives the composition of which is unknown or which are secret remedies. In doubtful cases consult your physician. 9. Listen, if you must, to the recommendations by friends and acquaintances of infallibly effective laxatives but don't act on their advice. 10. If you take an enema, don't distend the rectum with too much fluid. Avoid too cold or too hot injections. Add no irritating substances to the injection fluid. 11. Follow the constipation diet exactly in every detail. Even should it work unsatisfactorily or not at all, you will have gained the advantage that mild laxatives, formerly ineffectual, will now work well. 12. Do not abandon the diet too abruptly. Give it up very gradually and tentatively. When the constipation has lasted for years keep the principles of the constipation diet in mind for all time.

THE UNCONSCIOUS

The Unconscious Mind. By S. Herbert, M.D., M.R.C.S., L.R.C.P. London: A. & C. Black, Ltd. New York: Macmillan Company, 1923.

The subtitle, a psychoanalytical survey, clearly indicates the content. The author has added practically nothing to what has been written about psychoanalysis. In the main the book is a rehash of quotations with an attempt to orient the various schools of analysis. Yet from the point of view of American workers in psychoanalysis, the omission of the works of White, Jelliffe, Kempf, Burrow and others will seem incongruous, especially when careful consideration is given the reactionary works of Rivers and others, although they are fairly well evaluated. There must be some vital reason for the resistance of certain European analysts which is shown toward the work of the group of men in this country who have made contributions to the study of analysis. Perhaps the powers of the son are not relished by the parent.

PHILOSOPHY

Indian Philosophy. By S. Radhakrishnan. Volume I. New York: Macmillan & Co., 1923.

One of the few books on Eastern philosophy that is presented from the point of view of evolution. The material is handled much in the fashion in which Wundt handles his folk psychology. From the earliest Vedic hymns to the schools of Buddhism he traces each step in the evolutionary development of the various philosophical influence in India. True to his word, religion, as far as possible, is kept to one side or even in the background. The conditionings which influenced the changes which were effected are carefully considered and from many angles. Few writers have such a wealth of material so well organized and have the ability to present it as has Radhakrishnan.

In addition to the vast amount of material presented; the manner in which it is done is reminiscent of Frazer or some of the other gifted anthropologists. A certain honesty and fearlessness prevails. Courage on the part of a native is required to see and report regressive tendencies in a philosophy or a religion. This courage finds its reward, for such a man can then select the useful and reject the worthless. The most modern concepts of Eastern and Western philosophies are considered and compared. This comparison is carried out in a most intelligent manner. Of interest is the unconscious hypotheses of some of the Indian concepts of material things such as a highly complex solar system, as well as a fair idea of the atomic and molecular system.

When we consider how important Indian achievements are in our own life, we should find a vital interest in this interesting survey of their development. They are, as the Sanscrit grammar and language, the mother of all our modern languages. They did many things and thought many things which we are prone to neglect and which should be utilized by us today. We should not take a negative attitude and condemn all they have done because, on the whole, the originators of these teachings have regressed so markedly nor should we be led astray by the certain vital truths contained and start cults and fads based on these teachings. Many honest fakirs have done this, some to the extent of founding institutes of healing on the few thin threads they felt they had discovered. We must gather the products of the past to live more fully. But we must also remember Bergson's best sentence, "He who lives so much in the past that he cannot live in the future is dead."

HOSPITAL LIBRARY

The Hospital Library. By Edith Kathleen Jones. Chicago: American Library Association, 1923.

The subtitle of this book goes on to say that the work comprises articles on hospital library service, organization, administration and book selection, together with lists of books and periodicals suitable for hospitals. This last feature is by far the most valuable part of the book. The lists include fiction suitable for patients to read, and this is subdivided into old favorites and new, love stories and romances, humorous books, books that men like, including stories of adventure and daring, romances of trade and business, sports, animal stories, sea yarns, and detective and mystery stories; a selected list of books on general subjects, including handicrafts, followed by a list of first and second choice periodicals on the same general subjects. Then comes a list of books for little children, for older boys and older girls; a list of selected books for nurses, including biology, personal and community hygiene, chemistry and physics, dietetics and diet in disease, household and hospital economics, nursing, materia medica, therapeutics, pharmacology, drugs and solutions, massage and hydrotherapy, pathology, surgery, medicine, pediatrics and infant feeding, gynecology and obstetrics, neurology and psychiatry, general reference, and periodicals for nurses. The list for nurses was compiled by Mary N. Marvin, R. N. The final list is a bibliography of hospital library social service. There is a chapter on books suitable for reading

aloud to convalescents.

Medicoliterary Notes.

The announcement of the *Survey Graphic* for the coming year gives promise of a number of interesting articles on medical and psychological subjects. Among physicians who will contribute papers are Dr. Adolf Meyer, of the Phipps Psychiatric Clinic at Johns Hopkins; Dr. Ira S. Wile, of Mt. Sinai Hospital; Dr. Bernard Glueck, director of the Bureau of Children's Guidance in New York; Dr. Richard C. Cabot, professor of social ethics at Harvard, and Dr. Haven Emerson, of New York.

* * *

Dr. Charles V. Craster, health officer of Newark, writes for the November number of the *American Journal of Public Health* a full and interesting discussion of organic heart disease—its distribution and menace.

* * *

The Story of the Siren, by E. M. Foster, in the *Atlantic* for October, is well worth reading, both for its poetical and imaginative qualities, and for its psychological interest. In the same number Clifford H. Farr, professor of botany at the University of Iowa, has a paper on the Mind of the Molecule which gives interesting food for thought.

* * *

Grace Abbott, chief of the United States Children's Bureau, stated before a sectional meeting of the Home Economics Association in Chicago, that child labor in the United States is increasing. One million children between the ages of ten and sixteen years were employed in January, 1920, she said. A decrease was registered in 1921, but reports from twenty cities indicate marked increases for 1922, some as high as one hundred per cent., a general increase of fifty-seven per cent. being shown.—*Nation's Health.*

* * *

In a recent issue of *La Revue Mondiale,* Dr. M. A. Legrand discusses what he considers the extraordinary knowledge of medicine and surgery shown in the works of Homer. He is fully convinced that Homer was a real person and declares that only a trained and experienced practitioner could state so definitely in the descriptions of battles and combats the location of wounds, the course followed by piercing weapons, or the results of sword strokes.

* * *

An important recent publication dealing with the history of medicine is *Nosography in Modern Internal Medicine,* by Dr. Knud Faber, professor of internal medicine at the University of Copenhagen. The book takes up and discusses in full the various phases through which nosography has passed and the changing judgments on its value, giving a clear idea of the importance of the method for scientific progress.

* * *

Newspapers and journals would do well to follow the policy of the New York *World,* which publishes a circular distributed to all would be advertisers along medical lines stating the limitations imposed upon such advertisements. This circular states that the *World* does not accept advertisements which, in its opinion, are misleading, repulsive, or against public policy. These include advertisements of preparations, devices, or services that claim to work miracles, testimonials which are obscene or disgusting in text or illustrations, which might prevent or delay securing the needed attention of a physician or surgeon, or which propose surgical operations by any one other than a legally qualified practitioner.

* * *

A two year course in psychiatric social work is being offered by Simmons College, Boston. The first year covers work in behavior, psychopathology, and mental hygiene. The second year will be devoted largely to practical work, accompanied by lectures on the clinical side of psychiatry, with presentation of cases. The Boston Psychopathic Hospital and the Judge Baker Foundation will be used by the students for their field work.

* * *

What improvements in the sanitary quality of water supplies can do in lowering typhoid death rates is shown in New York City's typhoid fever statistics. For twenty-two years prior to 1906, the average death rate from this disease was twenty-two to one hundred thousand of population. Since 1906, there has been a uniform decrease, until in 1922, when it was three to one hundred thousand. This amounts to a saving of two thousand lives a year from typhoid fever alone.

* * *

In the course of naval operations in the Napoleonic wars, military surgeons discovered that the spread of sore throat among the men could be stopped by boiling mess gear.—*Monthly Bulletin, Boston Health Department.*

* * *

A recent report on industrial hygiene states that there are more than one hundred occupations which are more dangerous than coal mining. Among these are window cleaning, the operating of farm machinery, certain phases of carpentry, quarrying, and excavating.

* * *

The International Pasteur Centenary Exhibition at Strasburg is described in an article in the September number of the *World's Health.* From the descriptions and criticisms by the writer of various special exhibits, much of profit could be gained in the planning of health exhibits in this country. Fifteen countries besides France and her colonies had important special exhibits. "If one has any criticism to make," to quote from the article, "on stepping out of the last pavilion with aching eyes and brain dazed with figures, it is regret that the science of exhibiting has not kept pace with the advance of hygiene, and a feeling that there is still room for improvement in the attractive presentation of facts. . . . We are so eager to inform the public that we forget first to awaken their desire for information. We tell them that health means happiness, and then proceed to make them bored and miserable by presenting to them endless statistics which leave them with a confused idea of the awfulness of disease but very little conception of how to prevent it. Constructive hygiene exhibitions are what the public needs, and with the material we possess, there is no reason why we should not supply them."

Practical Therapeutics

FURTHER OBSERVATIONS WITH THE NEW NONNARCOTIC HYPNOANALGESIC

By M. A. Burns, M. D.,
Philadelphia,
Associate in Neurology, Jefferson Medical College.

That the symptomatology of diseases of the nervous system has attained a broader scope than the therapy is generally recognized, and therefore the value is enhanced of every drug that is demonstrated as a scientific addition to our resources. Nor is there another field in the practice of medicine where a drug requires such close scrutiny in affections so often characterized by chronicity, prolonged pain, and the various psychoses, as that of neurology.

In February, 1922 (1), I had the opportunity of reading a paper before the Philadelphia Neurological Society, embodying my preliminary observations with those of a number of other physicians, on the new nonnarcotic, hypnoanalgesic drug, allonal, representing a chemical combination of a new hypnotic, allyl-isopropyl-barbituric acid, and the analgesic element, phenyl - dimethyl - dimethylamino - pyrazolon (amidopyrin). Actuated by the promise of therapeutic value in the field of neurology which first experiences with allonal indicated, among them the results obtained during the spring and summer of 1921, by Dercum, reported by Gilpin (2), in a case of a malignant growth involving the cauda equina, associated with considerable pain which had resisted even morphine, I presented some observations on it before the society.

In addition to my own results in a series of cases furnishing rather severe tests, such as hemiplegia with insomnia, tabetic pains, cerebrospinal lues, multiple neuritis, rheumatoid arthritis, and melancholia with drug addiction, reports were included of cases treated by Wright, Stieglitz, Messmer, and Hornberger, likewise representing a great variety of affections, not all limited to the neurological field, but all with an array of symptoms in which pain and insomnia were the predominating factors.

Since these observations of about two years ago, reports (3, 4, 5, 6, 7) from other fields of medical practice have corroborated the conclusions which I drew at that time, as to the selective therapeutic value of the new drug; there have been important contributions, too, as to its value in the dental field, for allaying the fear of the dental chair on the part of very sensitive patients and for the relief of postoperative pain (8, 9).

In referring to these contributions, two factors are pertinent: first, that in each case the reports come from specialists whose investigations were made in selected cases of great severity, and secondly, that the outstanding indications were pain and insomnia—a syndrome which hitherto had been inextricably blended with the employment of opium and its derivatives.

In the meantime, it devolved upon me, as the first contributor on the subject, not only to take inventory of my additional observations, but to investigate the dose of the drug, untoward affects, if any, and, if possible, to look for a still greater scope of usefulness, especially the obvious one of drug addiction; and that not only, as to whether allonal in selected cases could replace morphine, but also, whether it could do so in the treatment of morphine addiction. In such treatment the omnipresent desideratum for neurologists was again uppermost, namely, to have a means for the permanent restoration of nervous equilibrium, by the lack of which we have been sadly handicapped so far. Even without further observation on my part, the answer to this appears to be forthcoming, when we consult one of the latest contributions on the subject, by Kuh and Gerty (3), of the Cook County Psychopathic Hospital of Chicago, and especially their results in the following types and number of cases, viz.: drug addiction, three; alcoholism, six; dementia precox, four; arteriosclerosis with and without dementia, five; neurasthenia, one; toxic psychosis, one; general paresis, five; taboparesis, three; cerebrospinal lues, two; polyarthritis and endocarditis, one; tic douloureux, one; neuralgia of the fifth nerve, one.

The therapeutic position of allonal thus having been established, the obviously logical field for immediate exploration was that of drug addiction, as indeed suggested by the case of melancholia with drug addiction, reported in my former paper. I may mention here that that patient continues to be perfectly well, has not taken any medicine whatever during the past eighteen months, is a perfectly healthy woman, and during that period has continuously held a responsible position in a large department store. This patient's daily consumption of four grains morphine sulphate had been cut out entirely and successfully at one stroke, by the substitution of thirteen grains allonal a day for several weeks and then by gradual reduction down to nothing. The results obtained in this case led to a wide use of the drug in the treatment of drug addicts in the Eastern Penitentiary in this city, and I am indebted to Dr. H. Ungerleider, resident physician in that institution, for the following report from his records:

"Seventy-two cases of drug addiction were treated with allonal in the Eastern Penitentiary State Hospital in the spring of this year. The treatment followed was one of rigorous substitution, all morphine, heroin, or cocaine being entirely cut off at once and allonal substituted. The patients were sustained by stimulation, the stimulants used being strychnine and plenty of highly nourishing food, milk, eggs, and all the sugar they asked for; the patients were allowed all the sweet foods they desired; allonal was given to allay insomnia and hyperexcitability, one tablet at a time, and no more than three tablets were given to any one patient. There were no complications. The patients all recovered and have been without any drug, either narcotics or allonal, since May, 1923."

Without the slightest suggestion of any claim that allonal has, as yet, been found a specific, I may say that it has, at least, proved a very useful drug for this purpose. The clinical tests to which it has been put in these cases were obviously more severe, in that they represented patients of a criminally in-

clined and institutional character, in whom the mental attitude and environments were hardly conducive to any psychological susceptibility to treatment.

Allonal, like many other drugs, will produce untoward, but not harmful symptoms, such as vertigo, if injudiciously administered, as, for instance, in overdose, in a dose too large for ambulatory purposes, and in those cases of idiosyncrasy always found, of which I, however, have not yet encountered any.

It is obvious that an hypnotic dose of any drug necessitates the recumbent posture. The therapeutic indications and the potentiality of a drug once having been established, the dose in a given case is entirely a matter of discretion, especially with a drug like this new one, the indications for which fluctuate from requiring an ambulatory sedative to demanding the induction of prolonged sleep, without narcosis, for the alleviation of pain. No one would administer a hypodermic dose of morphine for ambulatory purposes. This must be considered even in the case of a drug like allonal, although its effect is more under the control of the physician, and which does admit of administration by mouth for ambulatory purposes. Furthermore, in the case of this drug, the sensory and motor nerves, or both, are necessarily involved according to the dose.

During the past two years I have continued my observations on many of the patients to whom I had been giving allonal; no growth of tolerance for the drug involving an increase of dose in the treatment of chronic cases has been observed, indeed the results have been all in the other direction, as in the case of a woman, aged sixty-two years, who has been suffering from paralysis agitans for the past eight years. In addition to her marked rigidity and violent tremors, she suffered considerably from pain in her arms and legs; I had given her hyoscine and parathyroid for a long period, without results; her nights were terrible, on many occasions I was obliged to give her a hypodermic injection of morphine sulphate one quarter grain, sometimes this relieved her for four or five hours, but on many occasions the relief was of very short duration. About two years ago, I began giving her five grains allonal at bed time; she slept for five hours the first night and awoke with the same severe pain; finally I gave her ten grains at bed time, and she slept the whole night through, from eight to ten hours; her mornings after this dose were comfortable; although she was drowsy, she could be got out of bed and while her tremors and rigidity were not affected during her wakeful hours, yet she had comfortable nights. I gradually reduced the dose until now five grains produce excellent results. I feel this is a most unusual case, and this patient, who suffered continuously from severe pains and sleepless nights, is now comfortable except for her tremors and rigidity. Up to the present time, she has not suffered from any untoward affects as far as I can ascertain.

I now use allonal as a routine method of treatment for tabetic pains, and in cases of agitated depression I have obtained excellent results with two and two thirds grains after each meal and five grains at bed time during the agitated stage; up to the present time I have not had any difficulty in withdrawing the drug.

Some of my colleagues have kindly communicated to me for inclusion in this paper the results of their observations with the new drug:

Dr. F. X. Dercum tells me that "allonal undoubtedly controls neuralgia and other pains in a large number of cases, and that it is a remedy which is unassociated with any harmful effects."

Dr. J. Allen Jackson writes me that "since the publication of your paper on allonal I began the use of the drug in the Danville State Hospital, and I have been very favorably impressed with the results obtained. There is no question but that it is of decided value as a hypnotic and sedative in various mental disorders."

Dr. Charles S. Potts, of Philadelphia, writes: "In my experience with allonal I have used it in several cases of persistent hiccough with excellent results; it acted better than morphine. In what appeared to be a case of socalled Sluder's neuralgia, it controlled the paroxysms of sneezing and induced sleep."

Dr. Franklin G. Ebaugh, of Philadelphia, writes that allonal is of considerable value as an analgesic in tabetics, and states, "I also used it in cases of agitated depression and was quite pleased with the results. These patients were those who manifest constant agitation, moaning, wringing their hands, etc., which are so troublesome in our wards, especially the women's psychopathic. After allopal administration they were less agitated, cooperated better with ward routine and slept better. I hope to use the drug further in this type of cases."

Dr. George F. Phelps writes as follows: "Since the introduction of allonal for the purpose of relieving pain, and also for sedative and hypnotic effects, I can from my own personal experience feel certain that we have in this valuable drug a nonnarcotic of much value, especially in severe conditions where the dreaded hypodermic of morphine is used. I cite the following cases from personal experience.

"First, gastric crises in tabes, and the sharp lancinating pains so prominent in that condition.

"Second, mild and severe cases of insomnia.

"Third, during the menstrual periods I find it of great value, beginning three days before time.

"Fourth, in cases of neuritis, mild or severe.

"In each individual case I govern my dose according to the severity of the case.

"I might also add that during the past summer I had under my care a patient suffering from chronic prostatitis with a hypochondriac syndrome in which I used allonal with remarkable success."

Dr. S. F. Gilpin states "with a case of persistent luetic headache which was not relieved by morphine, ten grains of allonal gave a complete night's rest without any aftereffects the next day. In a case of brachial neuritis, which did not respond to other treatment, allonal was given every night for pain, produced excellent results and no aftereffects were noted and was easily withdrawn." Dr. Gilpin also states that allonal acts very well in cases of insomnia without pain.

Dr. B. F. Weiss cites the following cases: Case I.—Painful menstruation with distress and neurotic symptoms—ten grains every three hours, until relieved; symptoms subsided in the course of twelve hours. Case II—Trigeminal neuralgia following extraction of teeth, excruciating pains relieved by ten

grains every two hours, after three doses given. Case III.—Severe pains at onset of Bell's palsy—acute symptoms subsided after administration of allonal. Ten grains every three hours in the course of a day. Case IV.—Hodgkin's disease—nodules produced pain by pressure along superficial nerve trunks. Beneficial results from administration of ten grains every four hours—the only drug which during its use practically eliminated pain.

Dr. F. C. Becker reports as follows: "A case of tic douloureux in a male thirty-nine years of age. The condition existed for ten years. Allonal was administered as follows: ten grains at night, five grains in the morning running the dose up to thirty to forty grains every twenty-four hours. Gradual withdrawal after the use of the drug for eight or nine months. The patient has had no treatment and no recurrence of the tic since withdrawal about five months ago."

These experiences with the new drug in the period since its announcement in a previous paper in February, 1922 (1), confirm well the statement then made that "From the experiences quoted, it seems safe to conclude that the new drug is a remedy of real value for controlling insomnia and pain, and that it will enable us to get along with less of the narcotic pain allaying remedies." In addition, its use in the treatment of drug addicts has proved so beneficial as to warrant the hope that wide investigations will be made with it in this field.

I wish to thank Dr. F. X. Dercum, Dr. J. A. Jackson, Dr. C. S. Potts, Dr. F. G. Ebaugh, Dr. G. F. Phelps, Dr. S. F. Gilpin, Dr. B. F. Weiss, Dr. F. C. Becker, and Dr. H. Ungerleider for the reports furnished me and the kind permission to quote them in this review.

CYSTS OF THE PROSTATE AND AN UNUSUAL CASE SIMULATING VESICAL CALCULUS

By Geza Greenberg, M. D.,

New York,

Visiting Urologist to the Penitentiary and Workhouse Hospitals, Assistant Visiting Urologist to the Metropolitan Hospital.

Owing to the extreme rarity of this condition, little has been written about it in literature. I have encountered it but twice in my practice. In one of the cases it was discovered accidentally in the course of a routine examination, while in the other there were well marked symptoms resembling those of vesical calculus. I found it, therefore, of sufficient importance to add it to those already reported.

Before entering into a detailed discussion of these cases, it will be well to consider the genesis of cysts in general. A cyst represents a collection of fluid surrounded by a capsule. The capsular lining may be made up of, a, cubical or columnar epithelium; b, endothelium; c, ependyma cells; d, squamous epithelium, or, e, composite cells.

Cysts are formed by abnormal dilatations of preexisting cavities, as a result of secretion into them at a greater rate than absorption proceeds from them. They may be of antenatal origin, such as, thyrolingual and branchial cysts, due to the persistence of certain parts of the fetal ducts; on the other hand, they may be caused by incomplete development of ducts; the cystic kidney and the cystic liver are good examples of the latter. Then again, they may be acquired, due to obstruction of the ducts either from within or from without.

The acquired cysts comprise, 1, secretory cysts; 2, hemorrhagic cysts, due to the escape of blood and subsequent encapsulation; 3, necrotic cysts, due to local death of tissue with liquefaction and encapsulation, and 4, parasitic cysts, due to development of metazoan parasites within the organism, such parasites possessing a cystic or saccular stage of development.

When cellular activity leads to hypersecretion into a cavity unprovided with an outlet, or when that outlet is obstructed, then the fluid is secreted against a certain pressure. The pressure in general is low, only above that in the capillaries; but, as the secretion continues, and the absorption through the surrounding vessels and lymphatics is less rapid than the discharge into the cavity, there results a gradual distention of the cavity. *Pari passu* with the increased tension, there is an actual overgrowth of the lining epithelium and the fibrous stroma. Eventually, as the pressure increases, the nutrition of the lining cells is cut off. They, then, atrophy, and the cubical cells begin to flatten out. The watery contents of such cysts are slowly but constantly undergoing absorption; hence, they become more concentrated and assume a jellylike consistency.

Genesis of cysts in the male genital organs.—In the male, the mesonephros, or Wolffian body is represented by the paradidymis, and the Wolffian tubules by the vasa efferentia. Of the latter we recognize three groups; the main group constitutes the epididymis; the most distal tubules give rise to the stalked hydatids at the upper pole of the testis, or the globus major of the epididymis. The proximal remnants in connection with the lower end of the testis form a series of blind tubules, constituting the socalled paradidymis. Along with these and resembling in its relationship the Kobelts tubules (being blind distally, but communicating proximally with the efferent tubes) is the vas aberrans. To the blind tubules of the paradidymis are ascribed certain multiple cysts of the testis. Just as in connection with the Wolffian tubules in the female, there may arise parovarian cysts, so, apparently, from the vasa efferentia, the homologous organs, may arise solitary cysts, constituting what is known as encysted hydrocele of the testis, being distinct and different in origin from that of a hydrocele of the tunica vaginalis.

Of the Müllerian ducts in the male only two remnants have so far been determined, namely, the two ends, and of these usually only one, the distal or anterior end in association with the globus major of the epididymis, gives rise to cysts, forming what is known as the sessile hydatid. (Usually two such hydatids are present when exposing the testicle, one being the remains of the Wolffian duct, and the other that of the Müllerian duct.) The lower end fuses with its fellow of the other side in the substance of the prostate forming the sinus prostaticus, being the homologue of the uterus and the vagina, and situated between the seminal ducts. According to Adami (1).

this end never forms cysts, but clinical experience does not support this view. On the contrary, I believe, that congenital cysts of the prostate, from their position between the two ejaculatory ducts, point to their origin from the Müllerian ducts. Of the congenital cysts of the prostate the common ones would be those of the sinus prostaticus, as will be shown by the two cases to be cited. Small cysts of the utricle are, in all probability, not so extremely rare, as can be attested to by my clinical experience. I have casually, in the course of cystourethroscopic examinations, observed in not a few cases small cystic bodies protruding from the utricle which I have been at a loss to explain until recently.

Acquired cysts of smaller size within other parts of the prostatic substance are not so rare as the congenital ones, particularly in association with prostatic adenoma, but are usually too small to be felt by rectum.

Symptoms depend entirely on the location and the size of the cyst. In the majority of cases when small they may be accidentally discovered during a routine examination; if they are larger in size, to about one to two cm. in diameter with the capsule intact, they usually cause no symptoms. On the other hand, if the cyst ruptures and discharges a thick gelatinous substance into the urethra through a small rent in the capsule, then pain at the neck of the bladder, tenesmus and dysuria may follow as a result of it. If the cyst grows upwards toward the bladder, it may interfere with micturition like a prostatic adenoma, and may in extreme cases cause complete retention. Few such cases have been reported. The cyst giving rise to such grave symptoms is usually of hydatid origin. One such case has been reported (3). The symptoms in this case were those of urinary and intestinal obstruction. The authors could not differentiate prostatic tissue at all, as they were of the opinion that the prostate was entirely destroyed by the enormous cyst. It is stated by most English and French authorities that hydatids never occur in the prostate, but rather in the pelvis between the rectum and the bladder. The prostate, however, usually suffers complete absorption in those cases.

CASE HISTORIES.

The following two cases came to my observation, one of which was discovered by me accidentally about ten years ago during a routine examination in a patient who had no symptoms referable to the cyst. The other patient was seen by me recently, and presented definite symptoms caused by the presence of a cyst.

CASE I.—L. C., aged twenty-four, came to me in 1912 in the early stage of a primary gonorrheal urethritis. On examination I found a cyst measuring about two cm. in diameter in the substance of the prostate near its base, occupying the interval between the two ejaculatory ducts. This was not a retention cyst as it had been present the first day of his infection before there was any chance for the infection to travel to the prostate. He was free from infection at the end of six weeks without involvement of his adnexa. I have examined him since then from time to time to about a month ago. At that time the cyst was still there, being of the same size and presenting no symptoms.

CASE II.—W. S. C., aged thirty-five, married, father of three children, came to me on November 15, 1922, with the following history: Two weeks prior to date he had an attack of pain at the neck of the bladder, dysuria and terminal hematuria. This attack had passed off and was followed by another similar one ten days later. He was then referred by his physician to me. On closer questioning I elicited the fact that he had passed what looked like clots at the end of urination, but, in reality, was only a gelatinous substance. He, furthermore, complained of a chronic dull pain in the small of the back. The examination revealed a very large pendulous scrotum reaching to midway between the groin and the knee, and occupied by the most pronounced superficial and deep varicosities.

The examination of the prostate showed it to be of normal size, with a smooth and even surface. In the region of the base, and occupying the interval of the two ejaculatory ducts, was a cystic body with tense walls about two cm. in diameter.

The bladder was normal; both ureters patent in their entire extent, and the urine drawn from each kidney was normal chemically, macroscopically and microscopically.

The posterior urethra in the region of the colliculus seminalis was edematous with engorged blood-vessels; the utricle was occupied by a cystic swelling, a condition which I have observed a number of times prior to this. The floor of the right prostatic sulcus and the right lateral wall of the verumontana was raised and rounded as if impinged upon by a solid body from behind.

The x ray examination of the entire genitourinary tract, including the prostate for a possible calculus, was negative.

From the analysis of the symptoms and the physical findings, the symptoms can be easily explained. A cyst in the prostate like a cyst elsewhere is made up of fluid contents. The fluid, in the course of time, is either partly or wholly replaced by a colloidal or gelatinous substance. The cyst contents, when under great pressure, aided by muscular contractions, cause the cyst wall to rupture at a point of least resistance into the urethra, and as the contents are thick with but a small opening for drainage, colicky pains follow just as in any other hollow viscus which tries to rid itself of a foreign body. This constant dragging pain is accounted for by a pendulous scrotum and pronounced varicocele. The patient refused surgical treatment for either of the conditions. Proper support has relieved his backache, and the other symptoms traceable to the cyst have not returned.

Diagnosis.—When the cyst is of moderate size it can be easily palpated by rectum. It is a circumscribed swelling bulging into the rectum with tense walls. It has a well defined capsule and ordinarily any amount of pressure exerted upon it will not empty it of its contents, differing in that from a localized collection of pus in the prostate when near the urethra, which easily ruptures into it. In a cyst there is no tenderness either in the cyst wall or anywhere else in the prostate, whereas, in prostatic abscess there is excruciating pain and tenderness, constitutional symptoms, marked urinary symptoms, and usually, though not invariably, a history of infection. A cyst of the sinus prostaticus is always situated in

midline, while a prostatic abscess occupies either lobe, except when the entire prostate is involved in the suppurative process. Then the entire prostate is a large fluctuating mass.

Prostatic calculi are hard, often eliciting crepitations, usually forming within the sacculi of the gland and are, therefore, placed laterally instead of centrally. Their presence are often shown by the x ray.

Tuberculous nodules are harder unless caseation takes place. Then they are boggy and behave like a prostatic abscess. There may be other signs of tuberculosis elsewhere in the body.

Of the malignant growths sarcomata are of prime importance to be differentiated from cysts, for they, too, have a soft fluctuating feel; but they extend rapidly, running an acute course, and instead of growing toward the urethra, they have a tendency to grow into the rectum toward the sacrum, causing intestinal obstruction rather early, and, indeed, the patient may first present himself for relief of intestinal obstruction. One such case came to my notice at the Metropolitan Hospital.

Case III.—S. G., aged twenty-four, admitted to the Metropolitan Hospital as a transfer from another hospital on August 13, 1920. On July 10th of the same year he had been operated on at another hospital for intestinal obstruction where a large mass was discovered in the pelvis. He was then transferred to the Metropolitan Hospital. The examination of the prostate revealed an enormous soft swelling of the prostate, the examining finger reaching only to the left side of the growth under great difficulty, for, practically the entire rectum was filled with the tumor. In the same patient there had first developed urinary obstructive symptoms after his operation. The patient had become toxic and comatose for about four days prior to his death, which resulted on August 19th of the same year.

TREATMENT.

Treatment depends entirely upon the extent of the cyst, and the inconvenience it causes the patient. If it is small and merely discovered accidentally, it had better be left alone; if, on the other hand, it is large enough to cause distress, then one of three procedures is open to the surgeon, namely, opening the cyst through the urethra by means of the cystourethroscope and washing out the cavity. This, however, can be hardly considered curative. It may be applied to smaller cysts visible through the cystoscope but which are not palpable through the rectum. The second procedure is surgical, and this again may be conservative if the cyst is of the retention variety. Under this condition it may be treated like an abscess of the prostate, by incision and drainage through the perineum. If, on the other hand, it is of congenital origin, removal of the germinal layer must be resorted to before hoping for any cure. This is best accomplished by the open method employed for a perineal prostatectomy.

Treatment of Gonococcal Infection by Diathermy.—The reason for the selection of diathermy for the treatment of gonococcal infections by E. P. Cumberbatch and C. A. Robinson (*British Medical Journal,* July 14, 1923) is because the gonococcus can be destroyed at a temperature which is not high enough to damage the living tissues and because the diathermy raises the temperature of the tissues *en masse,* whereas other methods of applying heat raise the temperature of the superficial parts only. In almost all of the cases of gonococcal arthritis treated the pain was abolished, the swelling was reduced, and the range of motion was increased within a comparatively short period of time. Cases of gonococcal orchitis and epididymitis without exception quickly were relieved of pain and swelling after diathermy, even if the symptoms were severe. Convincing proof of the therapeutic power of diathermy in gonococcal infection was furnished by the disappearance of pain and swelling from joints or scrotum after the application of the treatment to the site of the original infection. Cases of gonococcal arthritis were freed from pain after after application of diathermy to the urethra and prostate, or urethra and cervix, without the inclusion of the joints in the treatment. There were also cases in which the application of diathermy to the joints did not procure much relief until the parts originally infected were included in the treatment. Diathermy was also applied to the urethra and cervix uteri in the female in cases in which these parts alone were infected. Such applications were followed by disappearance of the gonococci and cessation or diminution of the discharge. The effectiveness of the treatment was demonstrated by the failure to find gonococci in repeated attempts and the subsidence of arthritis after the application of diathermy, not to the joints but to the parts originally infected. Good results were also obtained in the treatment of prostatitis.

Experimental Observations on the Prophylaxis and Treatment of Syphilis.—Henry J. Nichols and John E. Walker (*The Journal of Experimental Medicine,* April, 1923) produced 100 per cent. of infections in rabbits by inoculating the scarified surface of both sides of the scrotum with suspensions of Treponema pallidum. By gland transfers from animals with positive local inoculations, 87.5 per cent. of takes were produced. These methods were used to test the prophylactic value of thirty per cent. calomel ointment, which proved efficacious up to eight hours after inoculation with syphilis. No marked differences appeared between the action of calomel in a base of lanolin and vaseline and in a base of benzoinated lard and wax. Five animals died of mercurial nephritis following prophylaxis with a large amount of calomel ointment. The method of gland transfers was also used for testing the sterilizing effect of arsphenamine and neoarsphenamine on old infections in the rabbit, with complete abolishment of the infection in every instance, whether by one, two or four doses. From the fact that by the most rigid tests available syphilis in a mammal has been abolished by arsphenamine it may be concluded that by sufficient treatment the same results can be accomplished in man.

Proceedings of Societies

SOUTHERN SURGICAL ASSOCIATION

Thirty-Fifth Annual Meeting, Held at Memphis, Tennessee, December 12 to 14, 1922.

Dr. C. Jeff Miller, of New Orleans, in the Chair.

(*Concluded from page 63*)

Autotransfusion.—Dr. Lucius E. Burch, of Nashville, Tenn., reported a case of splenectomy for splenic anemia. The operation was difficult and bloody. The large amount of blood that was lost in the abdomen during the operation was recovered by means of expressing the contents of the abdominal packs into a glass receptacle. A little over eight hundred c.c. of blood was recovered, and after this was citrated and strained through four layers of gauze, it was injected into a vein at the elbow. At the time the transfusion was started, the pulse was 140 and barely perceptible. At its completion, the pulse was 102 and strong, and the patient's color was good. There was no reaction following the transfusion, operative recovery was unusually smooth, and at the end of two weeks the patient was able to leave the hospital and return to his home. He had used this procedure in three other cases successfully, two of ruptured tubal pregnancy, and one a nephrectomy.

Brain Abscess.—Dr. Harry Hyland Kerr, of Washington, D. C., stated that brain abscess in general was difficult of diagnosis, and especially difficult of treatment. A study of some 120 cases in the literature of abscess of the frontal lobe showed nearly half of them undiagnosed until autopsy, and the mortality from this type in the neighborhood of eighty per cent. It was, therefore, incumbent upon us to study all cases with the greatest care. He reported six additional cases. Persistent headache with sustained leucocytosis, and especially the presence of retinal changes indicative of pressure in cases of drained frontal sinusitis or ethmoiditis, should demand exploration. Exploration by the two stage operation through a sterile field might be indicated. Direct drainage with a minimum of trauma should be established and not be disturbed until all symptoms had subsided. It was of paramount importance to drain a brain abscess too long rather than too short a time.

Factors of Safety in Thyroid Surgery.—Dr. Willard Bartlett, of St. Louis, Mo., said that during the last two years he had devoted special study to the problem of lessening mortality and shortening morbidity in the toxic goitres. He felt that this had been done in his clinic rather by a study of routine fundamental principles than by any technical improvements. In making a graduated approach to the final complete, double resection, as many as seven operative attacks had been made on a single individual. All patients were classified as to operative indications in the following five groups: 1, ligation of superior thyroid vessel group; 2, unilateral resection of the male subject; 3, unilateral resection of the female subject; 4, bilateral resection with wound left open, and 5, bilateral resection with complete wound closure. Three exceedingly important considerations were: 1, Anesthesia (one half of one per cent. novocaine infiltration with preliminary narcotics.) 2. The operation performed wherever the patient's nervous system was most protected. 3. The wide open wound in the highly toxic individual. Five considerations, above all others, influenced him in his estimate of the operative risk. 1. Myocardium. 2. Kidney function. 3. Metabolic rate (relative). 4. Weight (relative). 5. Selfcontrol.

Report of a Case of Ranula With Comments on the Thompson Theory of Origin.—Dr. V. P. Blair, of St. Louis, Mo., reported this case of ranula chiefly with the idea of reopening the discussion of Thompson's theory of origin. Two classes of mucoid cysts in and about the floor of the mouth occurred. 1. Relatively small cysts that appeared to lie in or just under the mucosa of the floor of the mouth or under the surface of the tongue which tended to protude frankly into the mouth. The origin of these is from various mucous or submucous glands of that region and in his observation were comparatively rare. Excision was a simple matter. 2. The type which lay in the floor of the mouth underneath the mucosa and submucous tissues and had what Thompson called a burrowing quality. These might push the tip of the tongue and the mucosa of the floor upward and backward, but the greater bulk always lay buried deep in the tissue of the floor. Removal was often difficult. The most commonly accepted hypothesis had been that such were obstruction cysts of the sublingual glands which presupposed a unique reaction to such obstruction. He thought Thompson's hypothesis, that the deep ranula and related cysts originated from migrated positions of the cervical sinus was sufficiently broad to explain all hitherto observed types. It offered at least a logical basis for adequate surgery. The case under discussion had a cystic mass on the left side of the floor of the mouth, seen from within the mouth, and also externally in the submaxillary region when she swallowed. The mass could be felt bimanually. Fluctuation was present. A swelling was also present on the right side, seen from within the mouth and apparently lost posteriorly in the neighborhood of the first molar. The swelling on the left side was approached from an external submaxillary region incision. A cystic mass protuded from the floor of the mouth behind the posterior edge of the mylohyoid muscle. The mass was dissected free from the hypoglossus muscle, inner internal pterygoid muscle and from the wall of the pharynx. On completion of excision, the right sided mass had disappeared.

White Bile in the Common Duct.—Dr. E. Starr Judd and Dr. John H. Lyons, of Rochester, Minn., said that the presence of a colorless liquid (without bile pigment) in obstructed common and hepatic ducts usually indicated increased operative risk, and in the Mayo Clinic series the operative mortality was twenty-one per cent. in spite of cautious preoperative measures and postoperative care, including calcium, transfusions, and so forth. They

believed that while the mortality was high, it was probably no higher than it would be in a series of cases of complete biliary obstruction of the same duration with green bile in the common and hepatic ducts. Their nineteen cases occurred among 649 operations upon the common and hepatic ducts in four years. In nine of these, the obstruction was due to stone in the common or hepatic duct and in six to trauma at a previous cholecystectomy; in two the obstruction was due to carcinoma (one of the pancreas and one of the ampulla), and in one it was due to pancreatitis. In one instance the white bile seemed to occur as a result of cholangitis. In no instance where the gallbladder was present, was it found to be normal. Seventeen of the nineteen patients were intensely jaundiced at the time of operation and there had been no recent decrease in the jaundice. One patient had a biliary fistula; one was not jaundiced, although there was complete obstruction to the common duct by stone. In this latter instance, cholecystectomy and cholecystostomy with removal of the stone resulted in drainage of bile on the fourth day postoperatively. The patient made an uneventful immediate convalescence, but died on the thirty-second day after operation, due to acute hemorrhagic pancreatitis. White bile occurred only when the obstructed ducts were not connected with a normally functioning gallbladder, and this fluid was a secretion of the mucosa of the biliary passages which occurred with obstruction when the secretion of the mucosa of these passages was greater than its resorption. The liver did not necessarily cease to secrete bile in these cases, although it was probable that the hepatic function might be suspended for a time in certain patients and entirely reestablished later.

Relative Value of Surgery and X Ray in the Treatment of Hyperthyroidism.—Dr. E. P. Richardson, of Boston, stated that in the present stage of our knowledge of hyperthyroidism, the most effective means of treatment were surgery and radiation. In the majority of instances improvement was due to the x ray. It had not proved possible to select the cases in which x ray would be effective. Cases of adenoma with hyperthyroidism were better treated by surgery than by x ray. Cases in which organic damage was present should receive the more certain detoxication possible with surgery. In early cases, x ray treatment for four months, during which the patient received ordinarily five treatments, might be carried out. The patients should be under supervision of a medical man familiar with this condition. The progress of treatment should be checked by determination of the basal metabolism. If promise of cure had not been obtained in four months, the patient should be treated surgically. The chief arguments in favor of the x ray were its lack of immediate risk and its possibility of indefinite expansion as a means of treatment. The ordinary objections to x ray treatment if carried out under proper control did not seem to him of great weight. X ray treatment, as given in his clinic, had not increased operative difficulty. The results of x ray in the patients apparently cured seemed satisfactory. In the cases where x ray frankly failed, the patients were willing to undergo operation, and no great harm was done. The patients who were improved but not cured presented the real difficulty. They were sufficiently improved to carry on their work, and yet retained a degree of toxicity which probably would lead to organic damage and shorten their usefulness. Yet they were unwilling to undergo operation. He believed that this class of patients, improved but not cured, presented the most serious argument against the use of the x ray in hyperthyroidism.

Treatment of Diverticulum of the Esophagus.—Dr. Charles H. Mayo, of Rochester, Minn., stated that according to the literature, only a few hundred patients with diverticulum of the esophagus had been operated upon. Although the condition was benign, the mortality had been as high as for more serious operations, such as malignant conditions in the abdomen. In one series of two hundred collected cases reported in the literature, there were sixteen deaths; in another of one hundred and nine cases, twelve deaths, and in one of one hundred, ten deaths after one stage operations, and twenty-eight fistulas. Some time ago Dr. Judd presented a record of fifty-two patients operated upon at the Clinic with three deaths. The number of cases had now been increased to seventy-four without further mortality.

Acute Atrophy of the Liver With Nodular Hyperplasia.—Dr. E. H. Pool and Dr. F. W. Bancroft, of New York, said that acute yellow atrophy of the liver was of some interest to the surgeon, because in the subacute or chronic cases the symptoms occasionally led to unnecessary and unfortunate exploratory operations, and because the operative findings in such cases were likely to be wrongly interpreted. Acute yellow atrophy of the liver was characterized by marked diminution in the size of the liver, which often became reduced fifty per cent. in less than two weeks. The etiology was obscure. The condition had been attributed to infection, to the action of some toxin, or to a combination of these two. Nothing, however, was actually known as to the character and source of the etiological factors. The disease occurred in apparently healthy individuals, as well as in those who presented some acute or chronic infection.

The symptoms developed insidiously and consisted for the most part in headache, digestive disturbances, such as vomiting and epigastric discomfort, jaundice, moderate fever, and later delirium, convulsions and coma. Many cases terminated fatally in a few weeks but some persisted for months. The clinical features usually presented a picture sufficiently definite to warrant a probable diagnosis and to indicate examination of the urine for leucin and tyrosin, the presence of which was strongly corroborative. On account of the rarity of the disease this was not often thought of as in their cases. The first significant pathological change consisted in fatty disintegration of the liver cells, as a result of which the liver enlarged. Rapid absorption of the products of disintegration followed with diminution in the size of the liver. The destroyed areas presented only connective tissues with large numbers of tubules like small biliary ducts. Localized areas of hyperplastic tissue devel-

oped, apparently representing a compensatory reproduction of the lost hepatic parenchyma. The appearance of the organ depended upon the stage of the disease. The hyperplastic changes were noted particularly in the prolonged cases and constituted a late feature. The lesion under consideration was of interest to the surgeon chiefly because of the great uncertainty and embarrassment which resulted when it was encountered at operation and not identified. They had each had such an experience. The liver, however, presented so characteristic a picture that the true condition should be identified.

Surgery of Acute Disease of the Gallbladder.—Dr. Robert Caldwell, of Nashville, Tenn., stated that every case of acute cholecystitis should be treated surgically, just as is acute appendicitis. Operation should be done as early as possible after the onset. The plan of treatment should be cholecystectomy when at all possible. The severe cases should be done the quickest way and with the least manipulation. The leaving of a clamp on the cystic duct and vessel would fill this requirement.

Sarcoma or Embryoma of the Kidney in Infants.—Dr. Charles R. Robins, of Richmond, Va., reported the case of an infant, male, twelve months of age, sent to him January 4, 1921, on account of a lump in the right side of the abdomen. The abdomen was distended and in the right side a globular tumor was found nearly filling the entire abdomen. It could be palpated posteriorly in the right kidney space and flank and seemed to be somewhat attached at this point, although freely movable. The pelvis and subcostal region appeared to be clear and the tumor projected anteriorly. A diagnosis of sarcoma of the kidney was made and operation advised, which was done two days later. The incision was made in the semilunar line, and on opening the abdomen the ascending colon and small intestine were found displaced to the left of the tumor. The peritoneum was incised external to the ascending colon and the kidney removed from its bed without difficulty. The pedicle was isolated and the vessels and ureter ligated separately. At the lower pole of the kidney an aberrant artery and vein were found to enter. These were ligated separately. There was comparatively little bleeding, which was easily controlled, the peritoneum was sutured, and the abdominal wound closed without drainage. The tumor was about the size of a grapefruit and sprang from the lower pole of the kidney. The upper portion of the kidney was quite normal.

Errors in Home Treatment of Appendicitis.—Dr. Fred W. Bailey, of St. Louis, Mo., stated that the virulence of appendicitis was not decreasing, because of careless and indifferent treatment. Many forms of appendicular colic were lashed into a fulminating process by purgatives. Patients would recover from the immediate attack if sanely treated and could then be operated upon without mortality. Until the exact pathology present in each case was known, it was impossible to prognosticate the outcome. The interval operation was a misnomer. The time to operate was at the earliest moment of positive diagnosis, provided a skilful surgeon was available and the environment satisfactory. As soon as careful examination had eliminated other diseases, removal of the affected appendix was indicated. If the process was acute and progressive and the patient's resistance low, release of the pent up pus through a gridiron exposure, under local anesthesia, was without shock and the surest method of reestablishing normal resistance. Was it not feasible to impress the public with these few facts and suggestions?—1. Abdominal pain, whether or not attended by nausea or vomiting, was a danger signal and should be treated with due respect. It might indicate anything from a simple colic to impending death. 2. The most effective premedical or home treatment included immediate and complete bed rest, nothing by mouth that peristalsis might remain inactive, positively no cathartic of any sort, and if, within a few hours, this treatment aided by a small low enema had not secured relief, transfer the responsibility to a physician.

Brain Abscess With Pathological Observations.—Dr. Charles Bagley, Jr., of Baltimore, Md., reported a series of twenty cases of brain abscess; seventeen patients were operated upon with a mortality of forty-six per cent.; eight patients operated upon and the three not operated upon died, and autopsies were performed in eight of the eleven fatal cases. He mentioned four types of the various methods of extension of infection from the primary seat to the secondary abscess in the brain. 1. The group in which there was an extradural abscess adjacent to the cavity of primary infection, of which there were three divisions. 2. When there was no visible tract of inflammation connecting the initial focus and the abscess cavity, the infection having been carried through the circulation. In some instances this was due to the lack of valves in the veins extending from the cerebellum into the sigmoid sinus, making possible the backing up of the infected contents of the sigmoid into the cerebellum. The same anatomical arrangement applied to the tympanic cavity and temporal lobe through the superior petrosal sinus. 3. That type in which there was introduced a foreign body, the tract of which remained open, acting as the abscess stalk. 4. That type in which the tract of entrance healed an abscess developed about the foreign body, the inflammation entirely limited to the position of the foreign body. In this group the abscess was secondary to injuries, such as a gunshot wound or severe blow, the cavity remaining in direct communication with the exterior of the skull.

Quinine Necrosis of Muscle.—Philip Figdor and D. Denham Pinnock (*British Medical Journal*, July 1, 1922) report an unusual sequel to the early treatment of malaria with intramuscular injections of quinine. A definite separation and encysting of the necrosed muscle has never been known to occur before, although the necrosis of muscle from such intramuscular injections is not rare. The necrosis was probably caused both by the direct action of the drug as well as by the pressure exerted by the injected fluid, great enough to cut off the blood supply of the muscle. The necrosed muscle acted as a foreign body and thus became encapsulated.

Abstracts from Current Literature

CARDIOVASCULAR DISEASES.

Radial Pulse in Intrathoracic Aneurysms.—C. O. Hawthorne (*British Medical Journal,* May 26, 1923) states that in order to be of diagnostic value the inequality between the sphygmographic and sphygmomanometric measurements on the two sides must be pronounced, and even then the possibility of a unilateral interference with the arterial circulation other than aneurysm must be remembered. Furthermore, marked differences are unusual even in cases of aneurysm, the readings on the two sides often being identical or nearly so. Neither unilateral delay in the pulse wave nor modification in the height or in the form of the wave is to be observed as a frequent clinical experience in thoracic aneurysm. The absence of such conditions from an individual case is therefore of little diagnostic import, and while their positive values, when present, may be considerable, even these are subject to marked qualification.

Indications and Modes of Administration of Ouabain.—Routier (*Journal de médecine de Paris,* September 22, 1923) maintains that ouabain is formally indicated in both paroxysmal and subacute manifestations of left ventricular insufficiency. The paroxysmal group includes acute edema of the lungs, atypical edema attacks, anginal attacks, and paroxysms of dyspnea, with or without pulmonary signs. The subacute group includes nonparoxysmal, persistent pulmonary edema, with repeated slight exacerbations; cardiac pleurisy; stasis manifestations, such as enlarged liver and edema of the extremities, and also the alternating pulse, tachycardia, bradycardia, and premature contractions. The drug should be given intravenously as soon as the diagnosis is made, in single doses not exceeding one fourth milligram, which may, however, be repeated once or twice a day for a number of days in succession, as the drug is not cumulative. Several thousand injections of one fourth milligram have been given by the author and his associates, without disturbance, provided the injection is made slowly and strictly into the vein. The injections should be continued until circulatory equilibrium has been completely restored. In one heart case having bilateral pleural effusion, the injections were continued for a month, until the effusions had been wholly absorbed. In some cases of left ventricular insufficiency, in which the indications were less urgent, satisfactory results were obtained by oral use of ouabain. In a case of aortic and mitral disease of rheumatic origin one hundred drops a day of a 0.2 per cent. ouabain solution were given by mouth for four days, then reduced to seventy-five drops, with good results. Ouabain by mouth may be used also in a variety of other conditions, but will fail unless at least one milligram is given in a single daily dose. Even two milligrams must be taken in a single dose to be effective, but larger daily amounts can be divided. One of the commonest indications for ouabain by the mouth is for the perpetuation of the effect of intravenous injections; when the latter are stopped, one milligram should be given daily at lunch in one dose, with or without the addition of 1.5 grams of theobromine. Ouabain by mouth complements and keeps up the effect of digitalis in valvular disease with more or less marked decompensation. In a case of auricular fibrillation in which digitalis, even in small doses, induced bradycardia, cardiac erethism, and consequent unpleasant symptoms when continued more than a short time, ouabain in a single daily dose of one milligram gave the best results during the two week intervals in which digitalis was temporarily discontinued. Ouabain by mouth can be advantageously given to assist the heart muscle in cases of high blood pressure—even without decompensation—in aortic arterial disease, and in paroxysmal tachycardia. In these cases, one milligram a day is given for eight to fifteen days in each month. It may with advantage be substituted for digitalis in acute diseases in which heart stimulation is required. In giving quinidine, a depressant to the heart muscle, digitalis or strophanthus should always be added. Ouabain by the mouth is very suitable in such cases, as it can be given in relatively large doses without toxic cumulative effects.

Syphilitic Myocarditis.—S. Bloch (*Journal de médecine de Paris,* September 22, 1923) notes that while the clinical picture of syphilitic myocarditis is variable, there is an ordinary form with manifestations similar to those of the average case of cardiac insufficiency, but occurring in a relatively young subject with either manifest or latent syphilis. A feature of the condition is that it comes on rather rapidly, in a few months or even weeks. The Wassermann reaction is always strongly positive, and this is very significant in a case in which the heart weakness can be accounted for neither by the kidneys, the lungs, high blood pressure, nor valvular disease. An important indication, furthermore, is that while the condition yields to heart tonics at first, it soon returns unless antisyphilitic treatment is given in addition. On the other hand, early and prolonged, though cautious, treatment may give results even more brilliant than those obtained in syphilitic aortitis. The recorded cases of cured syphilitic myocarditis are rather numerous. Aside from this commoner form, there is a latent form, detected only at autopsy; also a form with sudden death; a form resembling ordinary senile myocarditis, running a slow course, and monosymptomatic forms with lesions localized in certain "specialized" regions of the heart, with consequent Stokes-Adams syndrome, auricular fibrillation, or premature contractions of a certain type. In the treatment, heart tonics should be given first, and antisyphilitic treatment follow. Digitalis or strophanthus should be used after the usual preparation by drastic catharsis, venesection, and wet or dry cupping, according to the case. A milk diet should be ordered during the treatment with heart tonics. The digitalis effects may advantageously be supplemented with theobromine and a salt free diet. As soon as diuresis has been established, the pulse slowed, the heart sounds improved, dyspnea allayed, and proper sleep afforded, the antisyphilitic treatment should be begun. Hypodermic injections of soluble mercurials, such as the biniodide, may be given, provided edema

has disappeared. Neoarsphenamine in doses not exceeding 0.45 gram should not be omitted. Potassium iodide is a good auxiliary remedy. Bismuth, recently praised by Laubry and Bordet for syphilitic aortitis, seems especially indicated by reason of its efficacy, perfect tolerance, and gentle action. One patient who at first did not tolerate injections of three mils of bismuth iodoquinate solution on alternate days, did very well on two mil injections every three days.

Ventricular Fibrillation in Man with Temporary Cardiac Recovery.—Frederick A. Willius (*Journal of Laboratory and Clinical Medicine,* May, 1923) states that the case reported is the second instance on record of temporary cardiac recovery in man observed following ventricular fibrillation. The patient, a man forty-four years old, showed progressive cardiac failure. During the syncopal attack ventricular fibrillation occurred. The patient lived thirty-four and a half hours after this attack.

Atresia of the Pulmonary Artery in a Congenitally Defective Heart.—Walter Blair Stewart (*Journal of Laboratory and Clinical Medicine,* April, 1923) describes a female infant, four and a half months old, coming to autopsy, in whom the following interesting defects were present: Congenital atresia of the pulmonary artery, pulmonary valve and infundibulum of the right ventricle; origin of the aorta from the right ventricle; presence of a patent ductus arteriosus, and defective ventricular and auricular septa; complete cleft palate and right hare lip. The child was in fairly good health up to the time of death, and died only after a plastic operation had been performed prior to which she had shown intermittent cyanosis and attacks of strangulation.

Investigations on the Immediate Effect of Heavy Exercise (Stair Climbing) on Some Phases of Circulation and Respiration in Normal Individuals.—Christen Lundsgaard and Eggert Möller (*Journal of Biological Chemistry,* April, 1923) found that running up and down a flight of stairs once produced the same effect on the oxygen content of the venous blood as did running up and down five times. The oxygen content was low after the cessation of exercise. The effect on the pulse and respiration rates was markedly less after running up and down once than after five times. The oxygen content of the venous blood drawn from the arm showed no change after the subject had walked slowly up and down one flight of stairs, after riding a bicycle with brakes on for two to two and a half minutes, and after exercise with the arm (lifting a heavy load).

Prevention of Heart Disease.—F. John Poynton (*British Medical Journal,* June 2, 1923) emphasizes the weak points in the present management of rheumatic heart disease in the young and recommends the following measures which appear to be of service: 1, Improvement in medical instruction; 2, education of the public, particularly parents and school teachers, by propaganda and lectures; 3, further investigations into the incidence of chorea; 4, auxiliary country hospitals with a special department for cardiac children; 5, a schedule of suitable occupations for cardiac children; 6, a central bureau for purposes of organization, and in the far future an institution for research into and the study of rheumatism; 7, discrete treatment of local foci. The importance of careful treatment of local foci is also emphasized. The first attacks of rheumatic carditis, which constitute the most important group, are greatly improved by prolonged and skilful treatment during convalescence. With proper organization, the cases with recurrent attacks are more controlled and they are given a better chance of recovery. Physicians should learn to prevent much chorea and also more about the life history of the rheumatic child, thereby preventing many breakdowns during school life. These measures are the more valuable because the incidence of cardiac rheumatism is greater in the first fourteen years of life than at any other period.

GYNECOLOGY AND OBSTETRICS.

Isolated Torsion of a Normal Tube.—Benno Michel (*Zentralblatt für Gynäkologie,* June 4, 1922) reports one of the greatest rarities which has been reported only once before. The differential diagnosis was difficult. The woman, thirty-six years old, felt spontaneous, severe pains on the first day of her first puerperal period (1918), which recurred frequently without definite localization, especially at night after coitus or during the menstrual periods. Two days after the last menstrual period (four days previously) the patient felt a sudden, spontaneous, drawing pain in the rectum, associated with diffuse abdominal cramps. The abdomen revealed deep resistance in the right hypogastrium toward the midline and the vaginal examination revealed a tense fluctuating mass as large as a hen's egg, which suddenly disappeared on aspiration. The syringe contained both old and fresh blood. A laparotomy was done under the diagnosis of extrauterine pregnancy or a ruptured ovarian cyst with a twisted pedicle. At operation a bluish red, blackish brown, discolored tumor as large as an apple, which was adherent to the peritoneum, abdominal wall and rectum, was found to correspond with the left tube, which was markedly dilated in its ampullar portion and was connected with a normal left ovary. The pedicle itself, which consisted of the middle portion of the tube, was twisted more than twice three hundred and sixty degrees to the left and was markedly thinned out and had a glassy white color. Extirpation of the tube was followed by recovery.

Uterus Duplex Bicornis.—Wardlow and Smith (*Surgery, Gynecology, and Obstetrics,* October, 1922) state that malformations of the uterus are not uncommon, but a relatively small number are recognized. Pregnancy may occur in both horns of a uterus bicornis. Menstruation may occur during pregnancy in a bicornuate uterus. Statistics show frequent occurrence of twin pregnancy in this type of uterus. Malformations of the pelvis may or may not exist with anomalies of the uterus. Reports of uterine malformations should give complete history of menstrual function. Malformations of the uterus are frequently confused in diagnosing pelvic and abdominal lesions. When doing a hysterectomy in malformations of the uterus, always be careful to avoid injury of a misplaced ureter. The rectovesical ligament is confusing when first encountered.

Vulvovaginitis.—I. F. Stein (*Surgery, Gynecology, and Obstetrics,* January, 1923) states that vulvovaginitis is an infection which frequently is gonorrheal in origin, but may, even in purulent varieties, be nonspecific. Filth, unquestionably, plays a part in predisposing to the infection and may be the chief cause in the milder types. Diagnosis rests upon clinical evidence of the disease and smear examination made by an expert. Cultures prove positive in about fifty per cent. of gonorrheal cases and are therefore not requisite for diagnosis. Purulent vulvovaginitis should be vigorously treated by an approved method, such as that suggested by Gellhorn. A daily tub bath is an aid to local treatment and in mild nongonorrheal cases is all that is required for cure. Determination of cure rests upon the disappearance of clinical evidence of the infection, three negative smears at intervals of one week after suspending treatment, and a period of observation equal to duration of treatment.

Hysterectomy.—W. D. Phillips (*New Orleans Medical and Surgical Journal,* July, 1922) says that radium has removed the indications for hysterectomy in approximately forty per cent. of the cases. Myomectomy should be the procedure of choice in myoma of the uterus in young individuals. Supravaginal amputation of the uterus, or incomplete hysterectomy, should be the type of operation selected in the average case, providing the conditions justify it. Complete hysterectomy should be done in cases of myoma of long standing in which there is a tendency to grow rapidly, and in cases in which the cervix is diseased. Vaginal hysterectomy is the procedure of choice in cases of complete prolapse of the uterus in elderly individuals.

Therapy of Inflammatory Diseases of the Mucosa of the Uterine Body and Cervix.—Robert Joachimovits (*Zentralblatt für Gynäkologie,* November 4, 1922) found that ethereal oils are very useful remedies in inflammations of the mucous membrane of the genitals, namely, the cervix. Playfair sounds are wound around with cotton, dipped into a twenty-five per cent oily emulsion and introduced up to the internal os of the cervix. The introduction of strips of gauze, soaked in the oil, and left in the cervix for eight to twelve hours, are still more effective. This treatment was found particularly effective in local gonorrheal cervicitis. Adnexal conditions are no contraindications and erosions are not influenced unfavorably. This local treatment may be supplemented by the administration of ethereal oils by mouth or by enemas. The effect is undoubtedly due to the slow deep diffusion of the oils into the tissues as a result of the lipoid solubility, the production of a reactive aseptic inflammation and, possibly, to a specific action.

Functional Treatment of Dysmenorrhea.—As a result of his own animal experiments and the study of the literature, Fritz Ludwig (*Schweizerische medizinische Wochenschrift,* December 28, 1922) comes to the conclusion that dysmenorrhea should be considered as a disease of the tonus of the uterus; the conditions of contraction and relaxation are more or less affected by the internal secretions. Abnormal changes of contraction and relaxation, as well as continuous spastic contractions in the uterus, are chiefly responsible for dysmenorrhea. The normal tone of the uterus is kept at a medium level by the various internal secretions, just like the tone in the bloodvessels. Adrenalin sometimes shows a stimulating and sometimes an inhibitory effect in the same organism and it is therefore a regulator of the tone. A disturbance of the internal secretions (hypophysis, ovary, corpus luteum, adrenal, thyroid glands) consequently lead to dysmenorrheic disorders. Although organotherapy seems to be indicated it meets with great difficulties in practice. The substances that have an inhibitory effect on the tone are indicated, and of these papaverin (0.04 gm. three to six times) and benzyl benzoate are the best, possibly combined with narcotine, atropine, camphor, uzara, etc. Morphine and codeine are not indicated because of their stimulating effect.

Explanation of Twisting, Looping, and Knotting of the Umbilical Cord.—Hugo Sellheim (*Zentralblatt für Gynäkologie,* November 4, 1922) calls attention to the fact that if an ovum is placed in a glass vessel filled with fluid, and if this vessel is set in rotation, this motion will be transmitted to the ovum and umbilical cord; when the vessel is brought to a standstill, the ovum will undergo somersaults and the umbilical cord itself will untake many kinds of turnings and twistings. Human beings show abnormalities of the umbilical cord much more frequently than do animals, which is due to the fact that the former have a much wider range of motion in all possible axes of the body. The first stage of twisting, torsion, is the result of a simple turning of the fetus or umbilical cord on its pedicle as an axis, as in ovarian tumors. If the torsion is continued it results in looping of the cord as the second stage of torsion. If the continuous or repeated impulse to turning drives the loop against the fetus or the fetus against the loop, there results the third stage of looping or the knotting of the umbilical cord. Consequently all forceful motions, such as occur particularly in athletics and dancing, should be avoided during pregnancy.

Pyelitis During Pregnancy and the Puerperium.—Charles J. Currie (*Canadian Medical Association Journal,* July, 1922) says that pyelitis in the early months of pregnancy is not so uncommon as is supposed, and many cases escape notice altogether, both on account of the mildness of the symptoms and because the patient does not come under the observation of the obstetrician until the last months of pregnancy. These undetected chronic forms of pyelitis occurring during pregnancy may be the source of the acute trouble during the puerperium. There is great danger of mistaking pyelitis of the puerperium for acute sepsis. At least some of the abortive types of sepsis are cases of pyelitis which have undergone apparent spontaneous cure from the emptying of the pus from the pelvis of the kidney. It is necessary to make a careful uranalysis in all cases of suspected sepsis during the puerperium and of acute abdominal conditions in pregnancy. In acute cases with very high temperature the disease may run a rapidly fatal course, the patient dying in eight to ten days. But in the great majority of cases the disease shows a marked tendency to recovery under simple medical treatment, though relapses are said to be common. The treatment is simple in most cases. The patient should be put to bed so that the body

may be kept at an even temperature and the work of the kidneys reduced to a minimum. She should be kept on a fluid diet for a few days to help flush out the kidneys. The main object in medication is to see that the urinary tract is flushed out with alkaline solution and this object is best obtained by the use of potassium citrate in large doses, viz., from forty to sixty grains every two hours till the urine is alkaline when the dose may be reduced but never to the extent of allowing the urine to become acid. The urine should be examined daily to make sure of this. After all symptoms have subsided for three to four days it may be discontinued.

Urotropin is not of value in acute pyelitis and Kidd says that in some cases it is dangerous, asserting that in one instance it caused the death of his patient. In only one of this series was any of the more heroic forms of treatment required. This patient was treated with urotropin for three weeks before the alkaline treatment was given. The fever disappeared in a few days, afterward the potassium citrate was given, but the patient's general condition was so bad that it was felt necessary to induce labor. Urotropin and the acids are, however, of value in the chronic cases. Brilliant results are said to have been obtained by catheterizing the ureters and instilling silver salts into the pelvis. But this can only be done by one who is an expert in the use of the cystoscope and is not without danger in the presence of the pregnant uterus. In acute cases emptying the uterus may be necessary but is not often indicated nor always successful. The use of serums has not been satisfactory. They fail for the same reasons as they have failed in the case of septicemia. Autogenous vaccines may be of value in chronic cases.

Radiation of Pain in Lesions of the Fallopian Tube.—Maurice Marcus (*British Medical Journal,* February 3, 1923) states that lesions of the fallopian tubes cause pain which, arising in the iliac fossa, is referred down the front of the thigh to the knee. This distribution of pain is significant of an involvement of the tube and appears to be of diagnostic value. It suggests, further, that the tube is represented in the spinal cord by the eleventh and twelfth dorsal and the first three lumbar segments. With this sign a differential diagnosis between appendicitis and inflammation of the right tube may be made, the difference being that the pain of appendicitis starts usually around the umbilicus, and, felt later in the right iliac fossa, does not pass below the groin.

Retroflexion of the Uterus.—H. Meyer-Rüegg (*Schweizerische medizinische Wochenschrift,* January 11, 1923) states that women would be less troubled by disturbances due to uterine anomalies if physicians would agree to consider retroflexion merely as one of the various positions of the uterus. He gives the following conditions as to when a retroflected uterus should have its position corrected: 1, in some cases of sterility, in which no other cause for it is demonstrable; 2, in threatening incarceration in the fourth month of pregnancy; 3, when, as a result of an inadequate supporting apparatus, the uterus lies upon the levator ani muscle, extends into the genital hiatus and causes corresponding symptoms, even though they be of a partly psychogenic nature; and 4, as an adjuvant in the support of suggestion, when the psychotherapy has otherwise failed. In the first and second conditions, the correction ought to eliminate complications. In the third and fourth conditions, the associated peculiar condition of the nervous system should be looked upon as a complication, which can frequently be eliminated with the aid of the correction of the position of the uterus.

Symptomatology of Tubal Rupture in Extrauterine Pregnancy.—B. Herzfeld (*Zentralblatt für Gynäkologie,* March 31, 1923) states that in addition to the pain in the hypogastrium there may also be pain in the shoulder on the same side, apparently due to irritation of the phrenic nerve fibres in the diaphragm, as a result of the pouring out of fluid into the peritoneum. Furthermore, there is also a bladder symptom consisting of strangury, produced by the irritation of the peritoneum and the bladder by the tube, which is followed by collapse, presumably as a result of the rupture, which is favored by the increased intraabdominal pressure from urination.

Spontaneous Intrauterine Rupture of the Umbilical Cord During Labor.—Fr. Chr. Geller (*Zentralblatt für Gynäkologie,* March 3, 1923) states that the umbilical cord need not be ruptured at once, but there may be a rupture first of one artery, followed after several hours by the rupture of the other and the vein, so that fetal heart beats may be demonstrable several hours after the sign of the rupture, namely by a bloody amniotic fluid. The rupture of the cord is not dangerous for the mother or the child, provided it occurs after the delivery of the fetal head; if it occurs before that, the child can be saved only by immediate delivery. The causes of the rupture of the umbilical cord are a velamentous insertion of the cord, a short cord, and interrupted delivery of the fetal head.

Circular Tear of the Vagina.—S. Keszly (*Zentralblatt für Gynäkologie,* June 4, 1922) reports a rare case of direct trauma as the result of an accident. A virgin, twenty years old, fell from a height of one metre in such a manner that the neck of a bottle perforated her clothes and penetrated into her vagina. The entire vaginal tube showed a circular tear immediately behind the hymen and it was separated both from the paravaginal connective tissue as well as from the rectum and the urethra with inward invagination. Reconstruction of the vagina with sutures to restore the normal relationships was followed by successful healing.

Normal Amount of Blood in Pregnancy.—Georg Kaboth (*Zentralblatt für Gynäkologie,* March 31, 1923) compared the blood volume of eleven nonpregnant and twenty pregnant women. He found that the total blood volume in the nonpregnant women varied between 2805 and 4480 grams, or between 5.21 and 7.62 per cent. of the body weight. The total blood volume of the pregnant women ranged between 2982 and 4810 grams or from 5.96 to 8.5 per cent. of the body weight, after deducting the approximate weight of the fetus. The increase in the total blood volume was partly attributable to the increased amount of tissue. In the pregnant women near term and whose body weight ranged between fifty and seventy kilograms, there was an increase of 300 to 450 grams of blood.

Medicolegal Notes.

LIMITATIONS TO RIGHT OF CROSS EXAMINATION OF MEDICAL WITNESS BY MEDICAL TREATISES.

In the course of the trial of an action for personal injuries a medical expert, called by the plaintiff, was asked on cross examination if he had any authority to support certain statements made by him in the course of his cross examination. The witness named certain authorities and said they were at his home. A motion by the defendant for an order requiring the witness to produce the authorities was denied. Again, the same witness was asked to turn to a passage in a certain book referred to by him on cross examination, but the court refused to permit the witness to do so.

On appeal, the Circuit Court of Appeals, Ninth Circuit, Hoffschlaeger Co. v. Fraga, 290 Fed. 146, referred to the conflict of authority as to the extent of the use that may be made of medical treatise on the examination of expert witnesses, but found it unnecessary to consider the limitations of the rule, since counsel in this case did not bring himself within any known rule on the subject. "Clearly the court did not abuse its discretion in refusing to send the witness from the stand to his home to procure a book for the use of counsel, nor did it err in refusing to require the witness to examine a treatise to enable him to point out some line or paragraph that might support or contradict his testimony. If counsel desired to contradict the witness by some statement of the author, he should have called the attention of the witness to the statement, and not consumed the time of the court by asking the witness to look for something that might or might not exist."

PROMISE TO PAY DOCTOR'S BILLS FOR TREATING INJURED CHILD.

In an action for services rendered, the plantiff, a practising physician, claimed to have proved that the defendant, while operating his automobile, ran into and injured a child; that the defendant took the child to his parents' home and then to the plaintiff's office; that plaintiff informed defendant that the child was seriously injured and would have to be taken to a hospital and would require careful attention, and asked who would be responsible financially for the treatment, and the defendant immediately said, "I am responsible, doctor, I will pay all bills;" that the child was then taken to the hospital, where he was treated by the plaintiff for more than a month; that when the child was brought to the hospital, the matron asked the defendant if he would pay the hospital bills, and the defendant replied, "I will pay all bills;" and that subsequently at plaintiff's office the defendant stated to the plaintiff at one time that he expected to pay all the bills, and at another time that he would pay them and asked plaintiff to be as reasonable as possible, and plaintiff stated to the defendant that he would discount the bill if he would pay it without delay, which he promised to do. The defendant offered evidence to prove that he did not promise to pay or to be responsible for the services rendered, either at the time the child was in the plaintiff's office or at any subsequent time.

On appeal from judgment for the plaintiff, four questions were presented.

1. Were the circumstances such that a contract on the part of the defendant was to be inferred to pay the plaintiff for the services the value of which was sued for? The Connecticut Supreme Court of Errors answered this question in the affirmative. The defendant's express promise to pay was an original promise made orally upon the faith of which the plaintiff performed services. There were here all the elements necessary to a legal contract.

2. The plaintiff, in reliance upon the defendant's promise, performed these services which he was not legally bound to do, and this constituted in law a valid consideration for the contract.

3. The oral contract was not within the statute of frauds, since the defendant's undertaking was an original promise, and not a collateral one.

4. The action was properly brought under the common counts.

Judgment for the plaintiff was affirmed.—Douglas v. Brandt (Conn.) 121 Att. 179.

HOSPITAL INTERN HELD ENTITLED TO AWARD UNDER WORKMEN'S COMPENSATION ACT.

The New York Appellate Division holds, Bernstein v. Beth Israel Hospital, 205 App. Div. 419, 199 N. Y. Supp. 740, that a hospital intern is an "employee" of the hospital, within the State workmen's compensation act, and not an independent contractor. "Because the claimant was a physician," the court said, "he was not precluded from hiring to the hospital as an employee. He was hired for two years, and as compensation received his room, board, laundry work, and three uniforms a year—conceded to be of the value of $25 a week. If he failed in the performance of the duties assigned to him by reason of incompetence, or otherwise, he could be discharged." The decision for affirmance of the award to the claimant, injured by "infection and lymphangitis," was by a court divided three to two. The dissenting judges relied on Schloendorff v. New York Hospital, 211 N. Y. 125, 105 N. E. 92, wherein it was said: "The relation between a hospital and its physician is not that of master and servant. The hospital does not undertake to act through them, but merely to procure them to act, upon their own responsibility." Although the hospital had the power to discharge the claimant, the dissenting opinion said: "He was not a wage earner, but received his board, room, uniforms and laundry service as a concession to him, arising out of the necessity of his being constantly at hand under the rules applicable to his particular appointment."

EXPERT MEDICAL OPINIONS HELD TO SUPPORT FINDING AS TO COMPENSATION DISABILITY.

An appeal from an award under the Alabama workmen's compensation act, the claimant contended that the trial court erred in holding that fifty per cent disability to one eye was all the employer should be responsibile for, and complained that this finding was based upon the opinion of medical experts, which, according to the claimant's testimony, did him injustice as minimizing his injury.

Several medical men testified as to the impairment of the plaintiff's vision. Their opinions were based upon personal examinations of plaintiff and his statements made in response to the tests applied by them for the ascertainment of the facts at a time and under circumstances excluding every possible motive for misstatement. The Alabama Supreme Court considered that the depositions of these experts were far from evidencing mere "theories," and that no better evidence of the facts could be adduced. The consensus of the expert medical opinions, thus arrived at, was held to support the opinion of the trial court. Shaw v. Tennessee Coal, Iron & R. Co. (Ala.), 97 So. 694.

A Clinical Study of Pancreatitis*

JOHN B. DEAVER, M.D.,
Philadelphia, Pa.,
Surgeon in Chief, Lankenau Hospital; Emeritus Professor of Surgery, University of Pennsylvania.

By the character of the lesions of an organ given the most prominence in the average textbook, one is able to estimate fairly accurately the state of the medical knowledge regarding that organ, for the less we know of it the greater is the emphasis placed on its gross fulminating disease. The most notable example of this manifestation of ignorance even today is probably the pancreas, for little or no attempt is made to suggest means of diagnosing the common, milder lesions of this organ. It is extremely unfortunate that the emphasis is mostly placed on tumors large enough to cause obstruction of the bile duct, on acute hemorrhagic disease, and on desquamative processes, advanced enough to cause diabetes.

Until after the middle of the last century the functions and significance of the pancreas were almost neglected, but after the work of von Behring and Minkowski in 1889 demonstrating that extirpation of the organ was invariably followed by permanent diabetes, increased interest was shown in the gland, both as an organ of digestion and of metabolic importance. In this connection we must not forget the classical paper of Reginald Heber Fitz, published in the same year. The impetus to the study of the disease of this organ in this country was due to his pioneer work.

Progress, however, has been slow in the clinical recognition of the early changes in the pancreas, because of its situation in the midst of other important structures which mask its symptoms, and because extensive pancreatic destruction may occur before there is interference with function. This ability on the part of the pancreas to carry on its work in the body economy, even when gross lesions are present, is a very important factor to consider. Again, pancreatic derangement is often so closely associated with disease of the surrounding viscera, and the inaugural symptomatology is so evasive, that we are apt to overlook the fact that this organ is the seat of trouble.

The gland lies in the epigastrium, its head enclosed in the loop of the second portion of the duodenum and its tail in contact with the spleen. It thus extends across the spinal column at the level of the first and second lumbar vertebræ and rests upon the vena cava and aorta. The entire organ is retroperitoneal and it is attached to the parts behind it by loose connective tissue. Anteriorly, it is intimately attached to the posterior layer of the lesser peritoneal sac. Surrounding the pancreas is a fibrous sheath, which by its many extensions into the gland divides it into lobules. These lobules drain by small ducts into branches of the main duct—the duct of Wirsung, which descends just in front of the common bile duct to empty, usually with it, into the duodenum at the papilla of Vater. One of the large tributaries from the head, the duct of Santorini, connects with the duct of Wirsung as it turns downward, but in about fifty per cent. of cases it empties independently into the duct about three cm. above and anterior to the papilla, but keeps its connection with the duct of Wirsung. The blood supply is from the splenic, hepatic and superior mesenteric arteries and the venous drainage is all into the portal system. This very abundant arterial supply protects the pancreas against gangrene from occlusion, the necrosis in acute disease being independent of circulatory disturbances.

When we come to consider pancreatic disease in relation to anatomy, the most important items are the relation of the pancreatic duct to the common bile duct; that is to say, the enclosure of the common bile duct by the head of the pancreas, so that hyperplasia, or cicatricial contraction, or neoplasms of the head of the pancreas may obstruct the biliary outflow and give rise to pressure symptoms or even obstruction. The intimate connection of the pancreas to the great solar plexus, through the celiac, superior mesenteric, and splenic plexuses may explain the agonizing pain, the collapse and the frequently associated intestinal paresis in acute pancreatic disease and the close lymphatic connections of the pancreas to the liver, gallbladder, duodenum, and pylorus must always be borne in mind. Of this I shall speak later.

From the viewpoint of diagnosis and treatment the variations of the pancreas are not of great importance. The gland may surround the descending portion of the duodenum, or small accessory pan-

*Read before The American Congress of Internal Medicine, Philadelphia, Pa., April 2, 1923.

Copyright, 1924, by A. R. Elliott Publishing Company.

creatic glands may be found in the walls of the duodenum or the stomach. The former anomaly may result in constriction of the duodenum with obstruction, causing dilatation of the first portion of the duodenum and of the stomach.

The function of the pancreas is two fold, since it has both an internal and an external secretion. It is, as Sweet has said, a "complete selfcontained laboratory of physical chemistry." The internal secretion, the product of the islands of Langerhans, is concerned with the metabolism of carbohydrates and there is, perhaps, another secretion necessary for the absorbing function of the intestine. The external secretion is from the acini of the gland and empties at the papilla of Vater into the second portion of the duodenum. It is the most important of the digestive juices. The digestive activity of the powerful external secretions accounts for the essential feature of pancreatitis in its acute form. Bayliss and Starling have shown that the most powerful stimulant to pancreatic activity is a hormone, which originates in the intestinal mucosa by the action of the hydrochloric acid on a substance called prosecretin, which, becoming secretin, is carried by the blood stream to the pancreas.

Though, embryologically, the islands of Langerhans and the ordinary glandular tissue have their origin in the same entoblastic outgrowths, they apparently have no functional relation; for disease may, and usually does affect one without involving the other. Both are seldom affected except in cases of massive destruction, such as carcinoma or gangrene. This differentiation of function and the atrophy of one portion of the gland without damage to the islands has recently come into prominence through the work of Banting and his associates, in the treatment of diabetes with preparations of the extract of the islands after causing fibrosis of the rest of the pancreas by occlusion of the pancreatic ducts. This work was based on the observation made by many surgeons during the last few years, when they noticed fibrosis of the head of the pancreas following occlusion of the duct by gallstones, or by chronic inflammatory disease. This again illustrates that a knowledge of early or inaugural symptomatology is to be gained by early cooperation between the internist and surgeon and not between the internist and the autopsist, if I may coin the expression.

Until a large portion of the gland is destroyed and almost irreparable damage has been done, the function of the pancreas is not affected to such an extent that can be detected by any of our present methods of examination. However, from routine autopsy findings on individuals dying from all causes chronic pancreatitis is found to be a not uncommon lesion. The disease may be present in all stages from very slight fibrosis to one so extensive as to cause astonishment at the absence of significant symptoms during life, and, if present, the sign boards were certainly not correctly read. In operations on the gallbladder, the bile ducts and the stomach or duodenum, only too frequently the head of the pancreas is definitely indurated, and the surgeon realizes that procrastination in the discovery and removal of a focus of infection has led to a well nigh catastrophic ending. I wish that I might be able to send you all forth as disciples of the surgeon when it comes to interpreting chronic and acute upper abdominal symptomatology. There is only one way to be sure of what lies in the peritoneal cavity. And so, as the surgeon says, when in doubt drain, so I say to you, when in doubt send your cases to the surgeon. Stand at his elbow and have revealed to your own sight that which cannot be seen through the closed abdominal wall.

The close connection between disease of the biliary system and of the pancreas is being more and more emphasized; that is as it should be. If we could flash the picture of chronic pancreatitis before the eyes of every practitioner, who irrigates the duodenum of a patient suffering from gallbladder disease; and if the patient could return from the beyond and point his ghostly finger at his transgressor, perhaps we could look to the future with a greater degree of hope. But when calomel, castor oil, and epsom salts are still so frequently the armamentarium of the practitioner in a case of appendicitis, who fails to realize that purgation spells perforation, the outlook in a disease like pancreatitis is far from consoling and the millenium is indeed far off.

At first it was thought that the relationship between the hardening of the head of the pancreas and occlusion of the bile duct was due to the backing up of infected bile in the pancreatic ducts and to the spread of the infection from the ampulla up the duct to the pancreas. But it has been demonstrated at the Research Laboratory of the University of Pennsylvania that this route, known as Archibald's route, is the rarer method of transmission. The papilla of Vater is not always so arranged that infection can involve the pancreas through the duct of Wirsung. Chronic pancreatitis, therefore, is not due to transitory attacks of limited acute pancreatitis. To me it seems like tempting fate to open an abdomen and tinker with the papilla of Vater when the source of the trouble is easily seen in the open abdomen, usually in the form of an infected gallbladder. I urgently advise the surgeon and internist who cannot see this to consult our common friend, the ophthalmologist.

Chronic pancreatitis is usually limited to the "triangle of pancreatic involvement"—the tissue arising from the ventral anlage. It is extremely difficult to accept the duct theory unless the duct system in these cases fails to anastomose within the gland. Furthermore, what becomes of the organisms in those cases in which it is agreed the bile is definitely infected? On the other hand, the lymphatics of the head of the pancreas, which arise in the neighborhood of the bile duct, are intimately connected with the lymphatics of the lower end of the bile duct, and these in turn are intimately associated with the lymphatic ducts of the gallbladder. Infection of the regional lymph nodes thus can very easily cause a damming back of the lymph and aseptic inflammation of the interstitial pancreatic tissue, with subsequent organization and cicatrization; this, in fact, is the microscopic picture of chronic pancreatic inflammation and which explains the absence of pathogenic organisms.

The question of the pathogenesis of pancreatitis is a very important one. The retrojection of normal bile is, to my mind, never a cause of pan-

creatic disease, and only rarely does the retrojection of infected bile damage the pancreas sufficiently to cause chronic pancreatitis. The direct connection between the lymphatics of the liver, the gallbladder, the pylorus, the duodenum and even the appendix to the peripancreatic lymphatics was demonstrated by Dr. Pfeiffer and myself some years ago. The external evidence of such a close relationship can often be observed at the operating table in the form of an inflamed lymph node at the neck of the gallbladder, or along the common duct, and palpation of similar glands in the peripancreatic tissues. This is a peripancreatic lymphangitis and lymphadenitis, which is marching on to its deadly end as an interstitial pancreatitis, to prevent which simple cholecystectomy would have been all that was necessary. Later, prolonged drainage, sometimes over a period of months, if not years, will be required and even then the damage done is not entirely reparable. A patient of Dr. Riesman's upon whom I operated wore a T rubber drainage tube in the common duct four years.

From the foregoing remarks, it is evident that chronic pancreatitis per se is not easily diagnosed. The symptoms are usually those associated with the bile passages.

In the cases not associated with gallstones, the symptoms in about one third of the cases are those of cholecystitis, consisting of recurrent attacks of acute pain in the epigastrium and the right costal margin (occasionally the pain is in the left costal margin, the lumbar region, and possibly also all over the abdomen). Pain sometimes is referred to the right shoulder and back, but referred pain is not as frequent as when gallstones are present. Jaundice, flatulency, and vomiting form part of the picture and there is nearly always a history, more or less prolonged, of indigestion. In the intervals between attacks the majority of patients show subnormal acidity, and occasionally (in about seven per cent.) there is a glycosuria.

The jaundice is nearly always due to an associated lesion of the bile passages. But it may be caused by obstruction of the common bile duct by direct pressure from enlargement of the part of the pancreas which surounds the duct. Not rarely the jaundice in cases of enlargement and hardening of the gland is relieved by draining the gallbladder, or by a cholecystoduodenostomy. There is generally tenderness at the site of the most intense pain—usually the right costal margin. The pancreas can rarely be palpated.

The various functional tests are of value as suggestive or confirmatory evidence, but in the last analysis the diagnosis of chronic pancreatitis rests on the history and the clinical signs, but in the majority of cases can be made only by exploration. Carcinoma of the head of the pancreas is but one stage further in the progression of chronic pancreatitis. Inflammation spells irritation and irritation too often spells malignant degeneration. Fortunately, malignant degeneration of the pancreas is not very common for, unfortunately, we are not in a position to make the diagnosis clinically or even always able to make it at the operating table. Removal of a specimen of pancreatic tissue for frozen section diagnosis is too risky. In doubtful cases, all we can do is to give the patient the benefit of the doubt by establishing bile drainage either externally, or into the duodenum, the stomach or intestine.

The most important thing in chronic pancreatitis is prophylaxis, by early treatment of disease of the upper abdomen with which it is nearly always associated, and which leads to the chronic changes in the gallbladder. It may be all right to begin with medical treatment, but, if the condition fails to yield promptly, early operation is important in view of the irreparable damage that may take place.

While, for a body of internists, the chronic disease holds the greater interest, a few words on acute pancreatitis are certainly in order.

It is erroneous to believe that acute pancreatitis is necessarily associated with fat necrosis and hemorrhage, for experience has shown that it may occur as a simple nonsuppurative inflammation characterized by swelling, edema, and tenderness at the site of the organ. Usually, in this type, the head is the part affected, but the entire organ may also be involved in the process. These noninflammatory cases are sometimes described as pancreatic apoplexy. They are almost invariably associated with disease of the gallbladder, with or without calculi, or, possibly, the duodenum. While these observations may indicate a duct borne infection, there is little doubt that in the majority of cases the infection travels by way of the lymph channels.

Within the past decade there has been a marked increase in the number of reported cases of acute pancreatitis, so that the syndrome is becoming somewhat more familiar to the internist. But a correct preoperative diagnosis of acute pancreatitis is probably more rarely made than of the other acute abdominal disorders. First of all, it is not frequent, and outside of its exaggerated character, there is no one definite pathognomonic sign or symptom. Furthermore, it is nearly always associated with other severe abdominal lesions and, finally, the condition in the ultra acute case is so desperate that operation is resorted to without the formality of a diagnosis.

Diagnosis is possible if the patient is seen within the first thirty-six to forty-eight hours of the seizure. The onset is sudden, like a thunderbolt from a clear sky; the pain overwhelming, accompanied by persistent vomiting, rapid pulse and signs of collapse, more pronounced than in a perforating viscus. At first the temperature is subnormal and this is often suggestive. But, as the infection spreads, there is the usual rise in pulse and temperature which accompanies toxemia. Neither the abdominal distention nor the rigidity is so pronounced as in the other acute abdominal conditions. In the acute and subacute, as distinguished from the ultra acute case just briefly described, the attack is less dramatic, but demands the same immediate attention, especially because of the more favorable prognosis of operation.

Sometimes these acute cases recover without operation, but those that do would also, no doubt, have recovered if operated upon; while some of those that succumb without surgery might have been saved by early intervention.

I am of the opinion that many of the conditions diagnosed as acute indigestion, angina, etc., where the patient gives the history of having eaten excessively,

is stricken with sharp acute epigastric pain, followed by depression which lasts only for a short time and recovers in a few days, are instances of mild acute pancreatitis. The pathology in these cases is a very slight punctate hemorrhage into the pancreas. In practically all of them, a very careful physical examination and study will reveal, in addition to epigastric fulness, tenderness and often an indistinct palpable mass, a chronically diseased appendix or gallbladder.

The subject of differential diagnosis would take me too far afield, nor is it important in an emergency so definitely surgical.

In conclusion, I wish to impress upon you, if I have not already done so, the fact that pancreatic disease is the result of associations with bad company in the abdominal cavity. The pancreas suffers from continued insults from a diseased appendix, gallbladder, stomach or duodenum. I would, therefore, urge you to lead your patients away from these evil influences by early attention and removal of the primary offenders. The pancreas is a very important organ of digestion and a very essential part of the endocrine system. It is securely lodged within the abdominal cavity and cannot itself be removed. It behooves us, therefore, to give it every possible protection from assault from its neighbors, who so often behave very badly, and who can only be routed out by surgical methods.

1634 WALNUT STREET.

The Relation of Virulence to the Diphtheria Carrier Problem

DWIGHT M. LEWIS, M.D.,
New Haven, Conn.

To those who rely on the control of diphtheria carriers as the main factor in the prevention of diphtheria, some recent personal observations should prove of value. The present day opinion as to the control of the carrier rests upon the determination of positive virulence. A second generally accepted opinion is that in the localization of the organism, the throat diphtheria carrier dominates the carrier problem.

A review of our previous observations may make possible a better understanding of the observations to be presented and their relation to virulence, as well as to a number of apparently conflicting facts that are on record.

In an article published in 1916 (1), based on two years' experience in the field with this disease, it was shown that there were two types of carriers. One, the pharyngeal, constitutes about one fourth of the total carriers, and in general represents previous cases of the disease. The second type, the nasal, constituting three fourths of the total carriers, were either postconvalescent cases or socalled contact carriers with no record or history of having had the disease. Emphasis was laid on the fact that such nasal carriers presented to the eye a characteristic pathological picture. A second article (2) called attention to the clinical historical fact that nasal diphtheria always followed epidemics of measles and that an inspection of all convalescent cases of measles following an epidemic of the disease yielded nasal diphtheria carriers. Later (3), attention was called to the fact that, following trauma or operative procedures on the nasopharynx, as well as among subjects with septal deformities, nasal diphtheria carriers would come to the attention of the specialist and thus the spread of the disease would be prevented should such specialists investigate pathological nasal discharges. At the time we also emphasized the necessity of searching among contacts for the chronic nasal carrier, at one time a convalescent case, when the carrier who was discovered had never had the disease. We had at that time accumulated the evidence that an apparent immunity of many children in one family was due to multiple nasal carriership. In a subsequent article (4), two fundamentals existing in carriers were described, one relating to deformities of the nasopharynx, and the other relating to race. Predominating among Italians and Russian Jews, by virtue of the first fundamental, there was a practical absence among the Negroes with their racial absence of that fundamental. Other contributing factors were those of climate, dampness and absence of sunshine, and of sudden atmospheric changes as contributed to catarrhal conditions.

Based on the knowledge gained, and faced with an unusual frequency of diphtheria following an epidemic of measles, we recorded the experiences of a survey of upwards of thirty-five thousand school children during two months (5). Two nurses were shown a typical nasal carrier and instructed to search for such cases only. Thirty-four nasal carriers were found by these nurses and during the period twenty-three more nasal carriers were found by the department through school absentees. At this point it may be significant to contrast this survey, yielding two tenths of one per cent. school age population carriership, with the numerous recorded surveys constantly made from throat cultures, yielding anywhere from two per cent. upward similar carriership; and the accompanying observations that only one in ten of such carriers were virulent. We recorded the fact that of 117 carriers of that year (1917), twenty-five per cent. were under the age of five, sixty-three per cent. were between five and ten, ten per cent. were between ten and twenty, and two per cent. were over twenty. The following facts were also recorded: Five per cent. of the carriers were either known previous cases or gave a history of having been previous cases; in four instances a single carrier had made a further nasal carrier and in eight instances a single carrier had made either two or three further nasal carriers; in four instances the carrier was a recent case of measles, in two instances a recent case of grippe, in one instance was

convalescent from whooping cough, and in six instances was a chronic carrier of previous years. In the light of our later experiences, the history of a nasal carrier following measles, apparently infected by his mother during his attack, which gave rise to a case of diphtheria in a younger sister, is recalled as germane to the discussion. At that time we summed up the situation as follows: All individuals with acute catarrhal nasal conditions are potential carriers, needing only the presence of diphtheria bacilli to become specific carriers, their permanency being dependent on the degree of existing nasal obstruction; that individuals convalescent from respiratory diseases constitute the largest percentage of characteristic nasal carriers, and that, in general, cases of the disease followed the production of acute nasal carriers by chronic carriers.

During the past year we have had the advantage of a limited number of virulence tests on carriers. In addition to the investigation of suspicious nasal discharges, we have also investigated, by cultures, enlarged tonsils in convalescent measles as well as in contacts of diphtheria cases and of nasal carriers. With an incidence of 152 cases for the year under our observation, we have a total of 200 carriers. We have grouped in a table the essential features of relationship to virulence. The table follows:

	Kind of Carrier	Total number	Convalescent measles	" scarlet fever	" grippe	" whooping cough	" chickenpox	" case	Following A. and T.	No history obtained
Positive Virulence	Pharyngeal ..	4	1	—	—	—	—	—	—	3
	Nasopharyngeal	4	—	—	—	—	—	1	1	2
	Nasal	23	8	—	1	1	1	1	—	11
Negative Virulence	Pharyngeal ..	2	—	—	—	—	—	—	—	2
	Nasopharyngeal	—	—	—	—	—	—	—	—	—
	Nasal	33	—	—	—	—	—	1	—	32
Virulence Not obtained	Pharyngeal ..	13	—	—	—	—	—	—	—	13
	Nasopharyngeal	—	—	—	—	—	—	—	—	—
	Nasal	121	15	3	1	4	3	—	1	94

Due to the fact that opportunity for obtaining virulence tests was based, until late in the year, on the existence of carriership for upwards of one month, and an excess of eighty per cent. of the carriers were cured within two weeks, the results to be read from the table may seem of small moment of themselves. It will be noted that 88.5 per cent. of the carriers were nasal, two per cent. both nose and throat, and but 9.5 per cent. were pharyngeal. Our previous statistics working mainly on nasal discharges only, or other than among contacts of cases who had recently had sore throats, showed that three fourths of the carriers were nasal. It will further be noted that there is a small yet certain confirmatory evidence to our previous descriptive one, namely, that the clinical evidence of nasal carriers in those convalescent from other children's diseases was an important feature in seeking the characteristic nasal diphtheria carrier.

We are prepared to record the clinical finding that virulent pharyngeal carriers usually give rise to cases only through a third individual, namely, a nasal carrier. Not only does this confirm our previous observation, (*vide* nasal carrier, par. 4), but answers as well the frequently recorded instances of the numbers of virulent pharyngeal carriers found during surveys without actual cases. Interlocking with this point, a further factor that is fundamental becomes an issue. From the point of view of the laboratory, only virulent carriers are to be restrained. If not a convalescent case, said carrier would seem only able to obtain such virulent organisms from contact with an actual case. In the light of our field experience we have not been able to trace such a sequence. We can trace the following sequence. An avirulent organism from the nose or throat of an individual when conveyed to the nose of one ill with any of the usual children's diseases, becomes or may become virulent. Consequent on nasal deformity, the characteristic pathological picture follows. As illustrations we give the following instances.

Case I.—Family W., three children, two females, ages nine and six, one male, aged four. Female aged nine, nonresident during the period sister was ill with chickenpox. On convalescence, the latter was found with purulent, bloody, excoriating, unilateral, nasal discharge of at least a week's duration, while the male aged four had an even more intense, more recent unilateral nasal discharge. There was a positive virulence for the girl and a negative one for the boy. The latter had been for the past two years in a plaster cast for tuberculosis of the spine and had not contracted chickenpox. The source of the organism in the girl was clearly from a playmate of the same age across the street whom we had had under supervision one month previously, neighborhood or school cases of the disease being as definitely ruled out by complete absence.

Case II.—A second was as follows in family C, consisting of males aged nine, six and four, and an infant one month old. Clinical diphtheria was evident in the male aged nine, though initial cultures were negative. Asked to see the case for that reason, characteristic nasal discharges in both of the younger boys were sufficient evidence for immediate quarantine. The nose culture from the boy aged six was negative, while that of the younger brother was positive and a positive virulence was later reported. Copious nasal hemorrhages in the older carrier was evidently the reason for initial negative culture. Convalescent cultures from the case, as well as from this nasal carrier, were positive, in the latter for some two months, as well as in the younger brother. The history was that they had recently moved from another state where both younger boys had had whooping cough. There was satisfactory field evidence that the diphtheria organism had likewise been imported.

Case III.—A third instance was as follows: John M., aged nine, the oldest of a family of four children, was a nasal carrier in 1919 without associated cases in the family or neighborhood. In 1921, at a different address, the family was found with a reported case of diphtheria in Mary, aged nine. John and a brother Hugh, aged six, were nasal carriers at this time. This was the only case of diphtheria in the block during the year. In 1922 at yet another address following the report of a case of diphtheria, male aged four, a brother aged two was an evident recent nasal carrier. One of the other five families

in the house to show carriers, and the only one was the M. family, a recent arrival. Both John and Hugh were again characteristic nasal carriers. Virulence tests showed that neither were virulent. No virulence test was done on the brother of the patient as his carriership cleared within two weeks.

One further established fact merits consideration in this argument. It has been shown that children

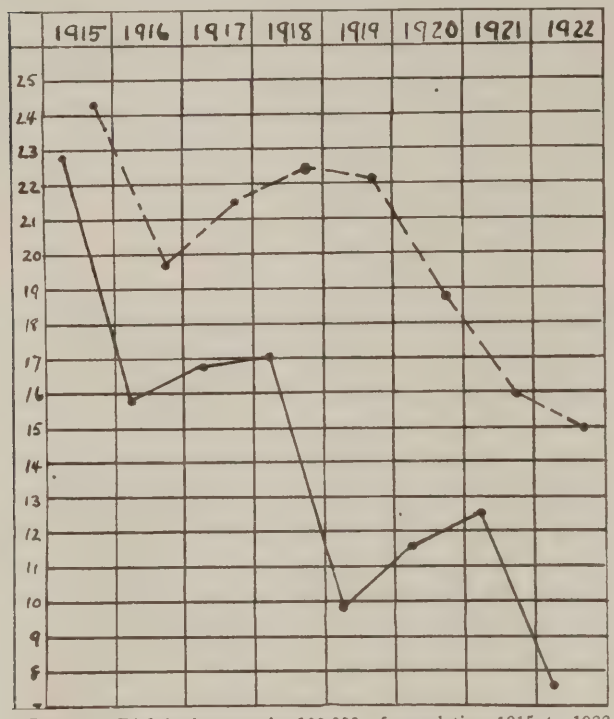

Chart 1.—Diphtheria rates in 100,000 of population 1915 to 1922. Solid line, New Haven, Conn.; broken line, New York City.

previously giving negative Schick reactions have given positive reactions during illnesses from measles, scarlet fever, poliomyelitis, etc. There would result then apparently, the elements for the cyclic frequency of the disease, diphtheria, and of the carriers; specific intercurrent diseases lessening the individual immunity to diphtheria for cases, and enhancing the virulence for carriers.

The logical conclusion from our observations may establish in the minds of many the fact that bacteriological evidence of diphtheria organisms in any individual, even when avirulent, should be a consideration as a source of possible future cases. Such, we believe to be the case under certain conditions. One main condition is that such carriers are frankly nasal and control should be had during the period of nasal discharge. The second essential condition is their control during times of incidence of measles, predominantly, and of operative procedure on the nasopharynx among contacts.

That it is sufficient for the continuation of increasing control of diphtheria, first, to investigate all previous nasal carriers, whether virulent or avirulent, during periods of increased respiratory disturbances (seasonal colds, for example), and, in the second place, to seek among their contacts for cases of convalescent respiratory disturbances and specific communicable diseases as may make virulent carriers in such contacts, would seem evidenced by our mortality rates for the period covered by our methods in contrast with a city where maximal equipment is provided for control of the communicable diseases. Such a city as New York is offered in comparison. The rates inclusive of those of 1920 are from the Census Bureau and for all years include nonresidents. Such a factor is of considerable moment for New Haven, the resident rate for 1922, for example, being 5.3. A graph for mortality rates in 100,000 of population for the past eight years is given in Chart I.

The results possible may be further shown by the morbidity and mortality rates for neighboring cities for the first six months of the year 1923, following the measles frequency of 1922. The statistics are as follows:

MORBIDITY AND MORTALITY RATES FOR DIPHTHERIA, JANUARY 1 TO JUNE 30, 1923, IN 100,000 POPULATION. NONRESIDENTS EXCLUDED

City	U. S. Census Est'd Popu.	Cases	Deaths	Morbidity	Mortality
Bridgeport	143,555	178	19	124	13.2
Hartford	138,036	209	10	144	7.0
New Britain	63,281	104	7	164	11.0
New Haven	172,967	58	1	34	0.6
Waterbury	97,952	143	6	146	6.1
New York City	5,927,617	4,659	349	79	5.9

Examination of the statistics for New Haven give further information. For the past three years a health centre has been in control of a population of 28,606 in 1922. During that year the morbidity and mortality, respectively, for measles for the district was 821.49 and 52.44. The corresponding figures for the remainder of the city under the direct jurisdiction of the Department of Health were 1,155.73 and 12.73. During the first six months of 1923 the health centre recorded sixteen cases of diphtheria with one death, while the remainder of the city recorded forty-two cases and no death. Inasmuch as the morbidity and mortality from diphtheria for the health centre district during the previous ten years has been much less than a slightly larger district of similar race stocks in the remainder of the city, the fact that unreported measles was not sought for and that measles was not used as a basis for obtaining diphtheria carriers, by the health centre, furnish critical data.

SUMMARY

Clinical statistical evidence of the past eight years in the study of diphtheria and the attempt to control it has shown and confirmed the following facts:

1. Pharyngeal cases and carriers of the disease are but slightly communicable compared with nasal carriers. The ratio of type of carriers may be as small as one to nine.

2. There is evidence that virulent nasal carriers, other than convalescent cases, may gain their carriership from avirulent organisms, and, in our experience, usually do gain their carriership in this way rather than from contact with cases.

3. There is evidence that virulent nasal carriers are made during or following the attack of certain specific communicable diseases, from contact individuals, in the main, nasal carriers of avirulent organisms.

4. The cyclic frequency of the disease is apparently referable (historically true as well), to the correlating frequencies of other specific communicable diseases, mainly measles.

The One Million Drug Addicts in the United States

A Defense of and Suggestion to the Medical Profession

S. ADOLPHUS KNOPF, M.D.,
New York.

Temperance in all things and the judicious administration of alcohol as a medicine and of opiates to assuage pain have been taught and practised by the medical profession since the time of Hippocrates. The United States Congress, for reasons best known to itself, thought it wise to enact a law to tell the physician what should be the maximum dose of alcohol he might prescribe. The prohibitionists are, of course, pleased and consider this act of Congress a wise measure. But now come the antiprohibitionists to the fore and say, "Because you suppressed the sale of all alcoholic drinks—beer and wine as well as strong liquors—the illicit use of narcotic drugs in the United States has increased 1400 per cent. during the past five years, the number of addicts has grown dangerously, and thus a most serious situation has been created." Whether or not the wets are correct in making this statement is still open to question, for there are competent authorities who maintain that in the sections of the country where prohibition is not strictly enforced there are just as many drug addicts as in places where it is most strictly enforced. Nevertheless, in reply to the assertion of the wets concerning prohibition's responsibility for the drug addiction, the Federal Prohibition Commissioner was quoted in a Washington news dispatch of December 26, 1922, as having said that, while the narcotic evil is always alarming, yet from a careful survey of the situation there seems to be no justification for the reports current as to its seriousness. "Prohibition headquarters," the dispatch further said, "is authority for the statement that estimates by those in close touch with the situation place the total number of addicts in the United States at not more than one million." Not more than one million! One per cent. of the total population of the country—one of every hundred persons in the United States.

I have gleaned these quotations from an article by Clyde Langston Eddy, vice-president of the American Pharmaceutical Association, which appeared in *Current History*, July, 1923, and in abstract form in the *Literary Digest* of August 25. This very illuminating and well written paper contains many accurate and generally known statements about the symptoms of drug addiction, its widespread use, its vast sociological aspects, the unwisdom of some of the antinarcotic laws, and the frequent desire of addicts to be cured, but who must in the meantime procure their narcotics from the dope peddler at exorbitant prices. There is, however, one statement regarding the etiology of drug addiction in which the author of that article is seriously mistaken, and I protest with all the vehemence possible against the assertion that "most persons, excepting, of course, the relatively small number of underworld hangers on, and others who use heroine or cocaine because their associates do, become addicted to the use of narcotic drugs as the result of having morphine or other opiates administered to or prescribed for them by their honest, if insufficiently informed, family physician."

Mr. Eddy quotes one case, that of a woman who had undergone a severe abdominal operation, and as a result had become an addict, and then continues to say that "there are thousands of similar cases. A patient suffering from the aftereffects of an operation, or from the ravages of cancer or tuberculosis, is given morphine over a period of a few weeks or months, and addiction results."

It is amazing that a man, who apparently has had some medical training, can make such a statement and rush into print with it. I have since talked with many colleagues—surgeons, general practitioners, and specialists—and only in the rarest instances could they recall any cases where surgical or medical treatment which cured the patient had resulted in drug addiction. As to the hopelessly ill tuberculous or cancerous patient, doomed to certain death within a short time, it would be cruel indeed to let such an one suffer. Judicious administration of opiates to these patients relieves their sufferings and thereby prolongs their lives at the same time. The great and immortal Osler, who was known as a nihilist as far as medication is concerned, called morphine in case of the hopelessly ill and suffering patient the G. O. M. remedy—"God's Own Medicine."

Surely, Mr. Eddy cannot classify these patients as drug addicts. Since he evidently bases his assertions on statistics, which, however, he does not quote, I may be permitted to quote some authoritative statements to refute the accusation that most persons addicted to the use of narcotic drugs owe their misfortune to their family physicians.

DRUG ADDICTION IN NEW YORK

In an interesting pamphlet by Dr. Carleton Simon, Special Deputy Police Commissioner of New York City, we read: "Less than two per cent. of five thousand addicts arrested by us in New York City were able to trace their drug addiction to having been acquired as a result of medical or surgical treatment; ninety-eight per cent. frankly confessed that their narcotic drug addiction was due either to bad environment, vicious influences, or criminal associations." The commissioner then continues by saying: "The statistics of our intensive campaign against this menace in the city of New York show that sixty-five per cent. of those arrested had a record on file in the Criminal Identification Bureau of the New York Police Department."

Some years ago, when beside my tuberculosis service at the Riverside Hospital there was established a service for the treatment of drug addicts, some committed there by police judges and some who had come by their own desire to be treated, my colleague, Dr. Thomas F. Joyce, was put in charge

of that division. From my own observation and inquiries, and from many a consultation with Dr. Joyce, I gained the impression that our profession was only responsible for drug addiction in the rarest instances. Dr. Joyce, whom I recently asked to give his authoritative opinion once more, wrote me as follows: "In the seven thousand cases that were under my personal supervision at the Workhouse Hospital and at the Riverside Hospital, during the examinations made by me for the etiological factors that led to their addiction, not more than a dozen patients attributed their habit to the injudicious use of narcotic drugs prescribed or administered by the physicians."

STARTING THE HABIT

Finally, I should like to quote from another admirable and instructive article on drug addiction by Dr. W. A. Bloedorn, which appeared in the last August issue of *Hygiea:* "The number of persons who begin the use of drugs through illness, insomnia, or persistent pain, while constituting a large aggregate, is believed to form a relatively small percentage of the total." In charging the regular medical profession with being responsible for the spread of drug addiction, I wonder if Mr. Eddy took into consideration the existence of the numerous cults in the name of which thousands of men and women are practising medicine, assuming the title of doctor.

The majority of the laity make no distinction between an M.D., representing regular medicine, and an irregular D. with all sorts of letters preceding it, indicating the particular cult practised. To the average individual such a person is a doctor. If this irregular practitioner wants to give prescriptions, including narcotics, all he has to do is to have some prescription blanks printed with the heading "Doctor So and So," his telephone number and any number he wishes to give after the letters "U.S.I.R.," and any druggist will fill his prescription for heroine, morphine, or cocaine. These irregular practitioners are rarely familiar with the science of materia medica and knowing little of indications, contraindications, or doses of habit forming narcotics, are without doubt responsible for not a few cases of drug addiction.

FAKE PHYSICIANS

Perhaps a serious source of drug addiction among the masses may come from the large number of individuals who have procured their medical diplomas fraudulently. Concerning this matter, the *Medical Times,* of January, 1924, very justly says in an editorial:

"Perhaps the worst phase of the fake medical diploma scandal is the part played by the graduates in the booze and dope situation. An M.D. who has purchased his credentials may be depended upon to engage in the liquor and drug traffic; he must be an essential accessory in this industry. Such activities probably overshadow his doings as a practitioner in the ordinary sense, and are presumably the prime reason why he seeks his bogus status."

So much for Mr. Eddy's charges against the medical profession as being responsible for the majority of our one million drug addicts, which he would place at an even greater number. Under the caption of Drug Takers in Every Walk of Life, Mr. Eddy maintains that "from one to four per cent. of all the people in the United States are addicted to the use of narcotic drugs." This would mean that from 1,100,000 to 4,400,000 morphine, heroine or cocaine habitues are constantly with us.

SUBJECT OF DRUG ADDICTION NEGLECTED IN MEDICAL SCHOOLS

I cannot refute Mr. Eddy's charges that in our medical schools the subject of drug addiction does not receive sufficient consideration. He quotes the information obtained from letters of inquiry sent out by a member of the Committee on Habit Forming Drugs of the American Public Health Association, as follows: "Of the eighty-five institutions, thirty-seven, or forty-three per cent., replied.

Among these replies were included the leading schools of the country. A brief review of the data so obtained indicates that the time devoted to the physiological, clinical, and therapeutic consideration of opiate addiction averaged about two hours, and that in several institutions the subject was not considered at all. In twenty-five of these schools the subject was taken up only under materia medica or therapeutics in the second year's course, and in nine schools, under the consideration of nervous and mental diseases. Clinical material was almost entirely lacking, none at all being available in thirteen of these schools, while in the others the replies stated that opportunities to observe cases were rare, infrequent, or limited to an occasional case seen in the insane asylums or jails. The textbooks used were, with but one exception, those which teach the old habit and vice theories, and in which treatment is confined to routine procedures and specific formulas. None of the more recent experimental or clinical work was mentioned. It is little wonder, therefore, that only 425 public health officials informed the Treasury Department recently that the physicians in their communities regarded addiction as a disease, while 542 of them reported that the medical men in their districts still looked upon it as a vice."

Let us, as a profession, honestly admit our shortcomings in this respect. Let our professors of materia medica in undergraduate schools devote more time and attention to the subject of drug addiction and have their theoretical teaching supplemented by a number of clinics where the students may learn all that is known of the etiology, symptomatology, and treatment of this disease; for drug addiction is a distinct disease and modern medicine recognizes the fact in all its bearings.

GOVERNMENT CONTROL

I cannot deal here in detail with the international and federal aspect of the problem. All I can do is to express the ardent hope that every civilized government will soon see to it that production, importation, and exportation of these drugs will be limited to actual medical needs. It is amazing to think that, according to statistics compiled during the year 1919, not less than 563,000 pounds of opium was imported, enough to feed each one of the entire population in this country forty grains. Deducting the fractional amount used for medical purposes, these figures give a fair idea of what is consumed by the one million addicts.

IMMIGRANT DRUG USERS

In a recent article in the *New York American*, the Hon. Frederick A. Wallis, Commissioner of Correction, advocates the exclusion of immigrants who are drug addicts, and quotes the latest statistics of other countries as compared with ours. The annual per capita consumption of opium in Italy is one grain; in Germany two grains; in England three grains; in France four grains. It is appalling to think that in the United States ten times as much is consumed as in France, which is the greatest opium consuming country in Europe, and this in spite of the fact that we do not cultivate the poppy plant nor the coca leaf for the production of narcotics. Commissioner Wallis is right when he said: "Drug addiction is eating at the very vitals of the nation. The congressional committee appointed to investigate the narcotic problem estimated that the number of drug addicts in the United States exceeded 1,990,000, or two per cent. of the population, four per cent. of the adults.

In a personal letter to me, Dr. Lambert writes: "What the big manufacturing druggists are doing, and where they are disposing of the enormous amounts (five hundred thousand pounds of opium a year) that are coming in, I do not know, nor does any one seem able to trace it, and Mr. Eddy's article is in my opinion a deliberate endeavor to throw the responsibility of the large number of addicts in the country on to the medical profession, instead of where it belongs, on the drug business."

The problem of the criminal addict has been admirably dealt with in Commissioner Simon's pamphlet referred to above. One of his most valuable suggestions is to the effect that each municipality should take care of its own addicts, index its narcotic criminals, and force them to take the cure, and also create an intercity identification bureau.

SOCIAL ASPECT

Mr. Eddy's article in *Current History*, as well as Dr. Joyce's paper on Denarcotizing the Addict, throw much light on the problem in its social, criminal, and general aspects. Interesting to the police and social workers, and in a measure also to the medical profession, is Mr. Eddy's deduction that upon the basis of the State Food and Drug Commission's calculation, in one of the States having stringent antinarcotic laws, the addicts of the country annually pay over $60,000,000 to be free from the dreaded withdrawal symptoms, most of this money going of necessity into the hands of illicit dealers, to whose financial advantage it is not only to exploit those who are already addicted, but constantly to create new addicts. Concerning these matters, what interests us, as physicians, now is particularly the etiology, prophylaxis, and treatment. If it is true that the habitual criminal is a product of environment plus mental pathology, then, as Commissioner Simon says, "it is doubly true of the narcotic criminal." Let us find means to discover the child, adolescent, or adult with a mental pathology, cure the curable and confine the incurable, or place him where the possibility of his obtaining the drug is entirely removed. We are advocating at present a universal annual physical examination of every man, woman, and child in the country. What an opportunity this would be to discover the mentally deficient! If our social workers could cooperate in such cases where home environment evidently needs to be investigated and improved, much good would be accomplished by preventive work. Drug addiction, too, may be discovered by this annual examination and when discovered properly dealt with.

RESPONSIBILITY OF THE PHYSICIAN

That physicians are rarely responsible for an individual contracting the drug habit, I have already endeavored to prove by quoting competent authorities who have made a special study of the etiology of thousands of cases. I shall now call attention to one fact which was evidently overlooked by Mr. Eddy in the reasearches which led him to accuse physicians of being responsible for the prevalence of narcotic addiction. There is not a single case on record in the New York Police Department where an arrested opium smoker admitted that the physician was responsible for his addiction. At my request, Commissioner Simon kindly looked up the records of his department for two and a half years. These records show that seven hundred opium smokers were arrested during that time and that all gave the cause of their addiction as bad association.

ADDICTION AMONG VETERANS

Against the specific accusation which Mr. Eddy makes by saying "Not a few veterans of the recent war are confirmed opiate addicts as the result of having morphine administered to them while recovering from painful wounds," I can speak from nearly two years of postwar work, which I was privileged to do in the former U. S. Public Health Service Hospital, later the U. S. War Veterans Hospital No. 61, at Fox Hills, S. I. Among the thousands of veterans sick and wounded who passed through and were treated at that hospital, it was a rare occurrence to find a confirmed drug addict who had become so as a result of treatment for his wounds or illness in military hospitals. The Surgeon Generals of the three services—War, Navy, and Public Health—are wide awake to the danger of drug addiction among their wards, and as one single instance concerning my own service I may mention that heroine, though in minute doses considered a valuable cough remedy, was not allowed to be dispensed in the service. Isolated cases where an exsoldier had been induced by dope peddlers to acquire the habit were of course found from time to time, but the dope peddler who is caught in the barracks or in the military or war veterans' hospital does not fare well, and our Veterans' Bureau is particularly watchful in this respect. General Frank T. Hines, director of the bureau, recently instructed all employees of the U. S. Veterans' Bureau to give every assistance to the narcotic forces of the government in running down members of the "dope" gangs who are living on the compensation received by disabled exservice men. All this shows, as has been said above, that the medical profession at large cannot possibly be held responsible for the existence of the alarming narcotic problem.

ADDICTION IN PRIVATE PRACTICE

Even if in exclusive consultation work or private practice, where one sees only the rich or socalled

better class of narcotic patients, the percentage of addicts blaming a physician for their misfortune is much higher than in public hospitals or penal institutions, the statements of those patients should be taken *cum grano salis*. Those aristocratic addicts will never admit association with the underworld or a *blasé* desire for new excitement as having been the true etiological factor in their acquisition of the habit. There may be, and there doubtless are, cases here and there where careless prescribing is responsible for an acquired addiction, but they represent an infinitesimal proportion of the existing number.

In order to keep our good record as military and civilian physicians let us continue to be careful and be even more careful, until not even one case can be in any way attributed to our prescriptions.

That education in our medical schools is urgently needed, I have already admitted and pointed out how it may be accomplished. Mr. Eddy is right when he says: "What is needed is an educational campaign that would reach police officers, judges, and magistrates, public health officials, professional reformers, members of legislative bodies and—ourselves." Mr. Eddy has, however, forgotten to mention a constituent of young people who need educational warning. It is well known that "dope bootleggers," as they are called, make it a point to create the nefarious habit among high school boys and girls, and even smaller children, in order to develop customers. This is done by mixing heroine or morphine with candy which is then sold in stores in the neighborhood of schools. There should be regular talks on the subject by competent teachers to warn our children of this danger. Even if it should not beset them now, the knowledge thus gained may mean a young man or woman saved from the habit later on. I have also wondered if such lectures in our prisons and reformatories would not be of great benefit in the prevention of drug addiction.

To come again to the education of physicians and fitting ourselves to help cope with this stupendous problem, besides instructing our students in all the medical schools what we know about this disease, let us also institute postgraduate courses where the same subject should be taught to the general practitioner. There is no question that this disease can be treated and successfully treated; not easily cured, I admit, and from my personal observation at Riverside, I am willing to subscribe at least in part to what Dr. Joyce said in a paper recently read before the New York Riverside Hospital Medical Society: "While the Health Department is in possession of hundreds of letters from grateful people who were apparently rescued from the pangs of drug addiction, I still insist that if there is any more destructive, more troublesome, more nervewrecking, more ungrateful class of patients to those intrusted with their care in our hospitals, we have not as yet met them." I know that when Dr. Joyce wrote this he had mostly in mind the rather undesirable class he met at Riverside and the Workhouse Hospital. Every physician who has had any experience at all with drug addicts will admit that there is also a better class of patients, a higher type of unfortunates, eager to be cured; and every narcotic addict who has a strong desire to be cured can be cured.

Unfortunately, there exists a relatively large number of unscrupulous concerns, sometimes presided over by physicians with diplomas, who promise sure cures in their institutions in an incredibly short time but who will retain the patient in their clutches as long as he has any money, doing him little if any good and working all the time only for their own financial gain. Again, "sure cure" remedies are advertised for sale for which the addict pays a high price but which prove to be worthless, if not harmful. The American Medical Association has a special research bureau to investigate all such frauds and frequently publishes scathing exposures of such socalled cures. The greater the publicity which is given to these fraudulent cures, the sooner will they be put out of business. Unfortunately, because the addict fears publicity, these criminal enterprises can but rarely be apprehended and prosecuted.

EXPERT MANAGEMENT OF DRUG ADDICTION

There are well qualified experts in this country, experienced in the treatment and management of drug addicts, who stand high in the profession. Rupert Blue, formerly Surgeon General of the United States Public Health Service; Senator Royal S. Copeland; Dr. Thomas F. Joyce, of the New York City Health Department; Professor Alexander Lambert, of Cornell University; Dr. Carlton Simon, Deputy Commissioner of Police, New York City; Professor William H. Welch, dean of the School of Hygiene, Johns Hopkins University; Dr. Butler, of the Shreveport Clinic, Louisiana; Dr. M. S. Gregory, director of the psychopatic division, Bellevue Hospital; Dr. O'Connor, chief surgeon, New York Department of Correction; Dr. Sherman, Kings County Hospital, New York; Hon. Augustine J. Smith, Deputy Commissioner of Public Welfare, New York City; Hon. Frederick A. Wallis, Commissioner of Correction, New York City, are some of them. The physicians among these men have treated many patients and are treating them successfully and lastingly. That there have been and will be relapses, and perhaps many more than are generally known, must be freely admitted; that there are many narcotic addicts who do not even care to become cured, is also true. Should we despair on that account? We have relapses in cancer, tuberculosis, mental and nervous diseases, and we have hopeless cases, but we continue our researches in all these diseases and do what we can for the patient, whether an original or relapsed case.

Even in the attempt to cure and redeem the addict having criminal record, we should not despair. Let us have the right conception of these socalled criminals. It is true that there are many criminals who easily became drug addicts because of being psychically inferior and mentally defective, and if they have become chronic criminals and chronic narcotic addicts, they should be chronically confined where they can no longer be a menace to society. But among the existing addicts there are also men and women who had high ideals and moral principles before they became addicts and who still have these ideals when their craving is satisfied. They forget all shame and honor when suddenly deprived of their opiates, and are ready then to lie, to steal, or to do worse things to get the means to procure the wanted drug; but they are not inherently liars

or thieves. Dr. Bloedorn puts it tersely in the article in *Hygiea* mentioned above, when he says: "The addict is not an addict because he has criminal tendencies; he develops criminal tendencies because he is an addict." The devotees of medical science have never been nor will ever be without mercy. In treating the addict who is also a criminal, justice, mercy and science must be combined. For the inducer, the peddler, the maker of addicts, the penalty should be severe enough to stop his nefarious trade forever.

There are certainly not a million diabetics in this country, and yet with what justifiable joy did we not greet the great discovery of Banting and how eager are the medical centres to teach the administration of insulin! Courses are offered to the general practitioner for acquiring the latest knowledge on the treatment of diabetes millitus by means of dietary regulation and the use of insulin.

DRUG ADDICTION COMMISSION

Why can not something similar be done on behalf of the one million or more drug addicts? The law which forbids the private practitioner to treat the drug addicts for a longer period than thirty days, and only permits continuous treatment in special institutions, is absurd, at least at the present time, in view of the large number of addicts and the small number of institutions. Granted even that Commissioner Simon's statement that sixty five per cent. of those arrested as drug addicts had a record on file in the Criminal Identification Bureau of the New York Police Department, should not be applicable to the entire country, the problem is nevertheless a criminal and social one, as well as it is a medical problem, and, by its vast distribution, not a local, state, or national, but an international problem.

In addition to the suggestion mentioned above, to appoint a commission to outline the best possible treatment for the narcotic addict and to deal with the problem of the cause and prevention, etc., I would make the following additional suggestion so as to avoid the possibility of even only an occasional unscrupulous physician abusing and violating his privilege by prescribing for drug addicts for financial gain. The commission should be authorized to grant special licenses only to such physicians who have, by their studies and experience, proved themselves to be competent to treat drug addicts. These physicians should be obliged to keep careful records of their narcotic cases and their methods of treatment, and the records should be subject to examination by the commission referred to. The county medical societies are perhaps best qualified to designate the men who by reason of their reputation and learning should be recommended to the commission as especially equipped for the treatment of drug addicts.

What an opportunity for our government or our great benefactors, the Rockefellers and other philanthropists, to be helpful in this work by giving financial aid in creating such a commission and such urgently needed courses in the best and most approved methods of treatment of narcotic addicts. Of course, there probably will have to be created many more institutions for temporary voluntary or compulsory confinement. Research bureaus and laboratories will also be necessary. The urgent need of an energetic combat of the problem in all its aspects is obvious.

INTERNATIONAL ASPECTS

Concerning the international aspect there seems to be hope now for serious work. To judge from a recent *News Bulletin* of the Foreign Policy Association, the opium question has made definite progress by the action taken by the League of Nations Assembly. In July there was some question as to the unanimous acceptance by the Council of the recommendations of the Advisory Committee on Opium. However, the Assembly has adopted the report and resolutions and has asked the Council to put them into effect. Two conferences are provided for by these resolutions:

First: A conference of governments in whose territories the smoking of opium temporarily continues, and the government of China.

Second: A conference of the governments concerned "to be held immediately after the first conference to give effect to principles submitted by representatives of the United States and adopted by the League with reference to the limitations of the amounts of raw opium and coca leaf to be imported for manufacture and for other medical and scientific purposes."

It is selfevident that the limitation of the output of habit forming drugs must be a matter of international cooperation. The *New York Medical Week*, January 5, 1924, puts the situation tersely in the following words:

"It is of no use for one country to control the manufacture of narcotics by its nationals if the illicit trade can be fed by the smuggled in surpluses of unrestricted regions. There is no doubt that narcotic drug addiction thrives on the growth and production of enormous quantities of these drugs over and above medical needs. While the revenue from this industry may amount to huge figures, the cost to civilization in social wreckage more than outweighs the monetary gains. The League of Nations is the logical agency through which to arrive at the needed international regulation of habit forming drugs."

In these international conferences the United States should take a bolder attitude and announce a policy of full cooperation in maintaining and operating the only international machinery for this purpose now in existence. In my opinion one or two of our leading medical men representing the physicians of this country should be sent to that conference, besides the federal representatives already there. Our profession, which is unjustly accused of fathering the narcotic problem, should be the first among those who are eager to combat it.

AN ALARMING SITUATION

Over a million drug addicts, many of whom are already confirmed criminals, in a population of one hundred and ten million is a fearfully dangerous and alarming situation. It will require the combined action of wise governments, enacting and enforcing rational antinarcotic laws, well trained physicians and experienced social workers, numerous special and well supervised institutions for the sanatorium treatment, large hearted philanthropists who will help to defray the expenses of so vast an undertaking, and lastly, but above all, education of all the people to the fearful consequences of drug addiction.

16 West Ninety-fifth Street.

Hiccough*

JULIUS FRIEDENWALD, M.D.,
Professor of Gastroenterology, University of Maryland
and MILFORD LEVY, M.D.,
Instructor in Neurology, University of Maryland
Baltimore, Md.

Hiccough is a symptom which may vary in degree from a slight, transitory, to a severe and at times, grave type. The underlying cause of this affection may be a trivial disturbance amenable to the simplest treatment, or, on the other hand, it may be due to the gravest form of organic disease, which, notwithstanding the most intensive and prolonged treatment, terminates in death.

Hiccough is manifested as a sound caused by a clonic spasm of the diaphragm producing a sudden inspiratory movement with closure of the glottis, which thus acts as a hindrance to the entrance of air to complete the vacuum produced by the rapid lowering of this muscle. Normally, the diaphragm and the abductors of the cord contract simultaneously, so that the aperture of the glottis widens as the air enters the chest; but when hiccough occurs with the clonic spasm of the diaphragm, there is no associated separation of the cords; in consequence of which the inrush of air against the partly closed glottis is prevented, giving rise to the well recognized sound to which allusion has been made.

The nervous mechanism entering into the production of hiccough is extremely complex; therefore, it will be best to consider hiccough as a type of modified respiration occasioned by irritations in the course of the vagus nerve. The vagus, through its origin in the medulla oblongata, has autonomous control over certain vital functions, chief among them being those of respiration, cardiac activity, ingestion, deglutition and digestion of food, circulation, metabolism and secretion.

The most frequent site of irritation of the vagus nerves is in the gastrointestinal tract. The nerves, upon being irritated, send out sensory impulses to the medullary centres, where they are reflexly transferred by way of the phrenics to the diaphragm.

Regarding hiccough as a modified type of respiration, it will be well to consider certain functions of normal respiration, as to the part played by the correlating centre in the medulla.

1. The muscle most active in the respiratory mechanism is the diaphragm, which is supplied, chiefly, by the phrenic nerve, the latter arising in the third, fourth and fifth cervical segments of the spinal cord.

2. The ordinary accessory groups, the external intercostal muscles and the intercartilaginous muscles, supplied by the first to twelfth thoracic nerves.

3. Extraordinary accessory groups, the long and short elevator of the muscles of the ribs, supplied by the dorsal branches of the intercostal nerves.

4. In deep expiration the abdominal muscles take part by compressing the abdomen. These are supplied by the eighth to twelfth thoracic nerves. It is probably that in extreme emergency few muscles of the body are exempt from respiratory effort.

5. There are certain muscular groups to serve to assist the respiratory act by increasing the capacity of the passages admitting the air. Depressors of the larynx, sternohyoid and sternothyroid muscles, supplied by the descendens hypoglossi nerve. The muscles separating the vocal cords, as the cricoarytenoid posterior and the thyroarytenoid, supplied by the recurrent laryngeal nerve, a branch of the vagus.

6. The depressors of the lower jaw, supplied by the hypoglossal nerve and pharyngeal plexus.

7. The levator palati, supplied by the pharyngeal plexus.

8. The azygos uvulæ, supplied by the pharyngeal plexus.

9. The dilator narium anterior and posterior, supplied by the facial.

10. The levator alæ nasi, supplied by the facial nerve (1).

The fact that so large a group of muscles may come into action to meet the requirement of respiration will give some conception of the diversified factors that may enter into the production of hiccough and the necessity of some coordinating centre which shall have control over the entire musculature, so that under extreme conditions, we may make use of these muscles in a most effective manner to meet the requirements of respiration.

It is the consensus of opinion that the respiratory nucleus is situated in the medulla oblongata in the gray portion of the reticular formation. Edinger states that this area is made up of bundles of fibres regarded as association cells. They possess short axons, which serve to bind different levels of the medulla to each other and therefore constitute association fibres. Probably the combined and harmonious activity exhibited by the nuclei of the vagus, facial and phrenic nerves in the process of respiration is established by these fibres, which have definite control over all impulses, influencing the principal and accessory muscular mechanisms of respiration, which are ultimately delivered to the coordinating nucleus of the medulla oblongata.

Not only does this nucleus come under the immediate influence of the reflex activity, but also is controlled from the cerebral cortex by voluntary impulses. By its connections sensory elements of the cranial nerves, it responds to stimuli received by the receptors in the mouth, pharynx, larynx, and lung, as well as in the nasal passages. There is probably also some cutaneous sensory connections with this centre as is evidenced by the effect on respiration of pain or extremes in heat or cold.

The chief source of stimulation of the respiratory centre in the medulla oblongata is the venosity of

*From the Gastroenterological and Neurological Clinics of the Department of Medicine, University of Maryland.

the blood. The greater the venosity of the blood, the greater the stimulation of the respiratory centre. Certain products of metabolism seem to activate this centre, as is evidenced by yawning in fatigue, etc. There is a possibility that certain toxic products of metabolism, or from microorganisms in this way, produce hiccough by direct action on the respiratory centre.

Upon physiological basis, Knapp (2) assumes a cortical centre for diaphragmatic movements inasmuch as, clinically, an irritation of the diaphragmatic centre in one hemisphere produces bilateral symmetrical diaphragmatic contraction. He states that the cortical centre for the diaphragm lies in the upper half of the foot of the second frontal convolution in front of the lower part of the leg centre and centre for shoulder movements; close to the centre for the abdominal muscles and, according to Becterew, in the region of the respiratory centre.

Modifications of respiration in laughing and crying, which result from excitation of the higher centres, particularly those that have to do with the emotions, would lead to the belief that some of the cases of socalled psychic or hysterical hiccough may be due to overstimulation of these centres.

The reflex respiratory act in which stimulation of the olfactory nerve causes temporary cessation of respiration is well known. Sudden unexpected sounds, producing stimulation through the eighth nerve, probably in conjunction with the emotional psychic centres, produce a similar result.

The number of spasmodic contractions of the diaphragm occurring in this condition may vary from one to twenty a minute, though occasionally they may reach a far higher number, occurring not only by day, but also during sleep, producing exhaustion and pain in the region of the diaphragm and at times interfering with the respirations and with deglutition.

ETIOLOGY

Varied factors enter into the etiology of hiccough. They may be classified under the following headings:

1. Neurotic and unknown causes.
2. Reflex.
3. Infectious and toxic.
4. Affections of the thoracic viscera.
5. Affections of the abdominal viscera.
6. Cerebrospinal and other organic nervous diseases.

1. *Neurotic and Unknown Causes.*—Under this heading may be classified a large group of cases, the origin of which is unknown, developing without apparent cause; as well as those cases observed so frequently in hysterical and neurotic individuals, following excitement, worry and sudden fear. We are reminded of a young woman, nineteen years of age, of a rather hysterical type, who, while on shipboard during a period of danger from fog, developed an incessant hiccough, which persisted day and night for a period of two weeks and then disappeared suddenly without cause. Bassler has also classified under the head of a pure neurosis a form of singultus associated with hyperesthesia of the stomach, or with gastralgia.

2. *Reflex Causes.*—Reflex causes are important factors in the production of hiccough. Such conditions may be brought about by exposure to wet and cold, though it is possible that under these conditions a neuritis of the phrenic nerve may be the primary factor. This affection may also be occasioned by food ingested at too high or too low a temperature or too highly seasoned. It may occur as a result of shock from operation even though the abdomen itself has not been involved, as one not infrequently observes hiccough following operation or instrumentation on the male genital organs. It is frequently noted in the early stages of coryza and not uncommonly as a result of intestinal parasites.

3. *Infections and Toxic Causes.*—Infections and intoxications play an important rôle in the production of hiccough. Of the infections in which this condition is not uncommonly observed, the following may be noted: septicemia, influenza, pneumonia, typhoid fever, relapsing fever, cholera, severe forms of malaria, and acute rheumatic fever. When singultus occurs in septicemia, it is a serious omen and is not uncommonly indicative of a fatal outcome.

It is not infrequently noted in influenza and in our experience occurred in two forms in association with the recent epidemic; first, during the acute stages of the disease, accompanied by a congestion of the respiratory tract and with an intense bronchitis, subsiding with the disappearance of the inflammatory affection, and second, following recovery, not uncommonly in individuals apparently in good health.

The two following cases occurring in our experience briefly illustrate the two forms:

Case I.—T. J., aged forty-three years, male, who had always enjoyed good health, was suddenly attacked with chills, pain in the chest and fever, during the epidemic of influenza of two years ago. The patient became prostrated and weak, with a temperature of from 101° to 102.5°; pulse 90 to 110 a minute, and respirations 24 to 28 a minute, for a period of nearly three weeks. During this period there were definite evidences of areas of bronchopneumonia in both the right and left chest. After the first week hiccough began occasionally to manifest itself, gradually increasing in number and intensity so that for the remaining two weeks during which fever was still present, it was almost incessant both day and night, not being materially influenced by any remedy; however, as soon as the fever had subsided, it disappeared permanently. It is quite possible that the associated toxemia played the rôle of causative factor in this case.

Case II.—In the second case, the patient, W. M., male, aged fifty-eight years, six weeks previous to his present affection had had a moderately severe attack of influenza without serious complications. Without a known cause, during an epidemic of hiccough in the locality, he began with a moderate attack of this affection, which gradually increased to a severe degree, being present both day and night. A careful examination produced no apparent cause for this condition, the patient meantime revealing signs of weakness and exhaustion and it was only following a hospital treatment of three weeks, during which all the usual remedies were employed, that this condition subsided. The patient has since remained well.

Epidemic hiccough has been produced experimentally by Rosenow by injection into the cerebrospinal system of laboratory animals, the nasopharyngeal washings from patients suffering with the disease. No definite lesions in these experimental studies have

been demonstrated either in phrenic or vagus nerves. Nevertheless, the gross pathological changes in the brain and spinal cord, so closely resemble the findings in lethargic encephalitis, that Rosenow considers epidemic hiccough as a variety of this condition.

Hiccough occurs at times during the course of pneumonia, as a rule, however, in the gravest forms associated with severe toxemia, and is frequently a terminal sign.

In typhoid fever hiccough may appear either as a sign of peritonitis due to perforation, or may be indicative of a serious toxemia. In a young man (N. G.) of eighteen years with a severe attack of typhoid fever, with marked toxemia but without serious complications, this symptom appeared during the fifth week of the disease and persisted by day and night notwithstanding all attempts at relief. The hiccoughs became so violent that death appeared imminent; but the condition was apparently relieved by direct galvanization to the phrenics. In relapsing fever and cholera, singultus may become extremely serious, and may continue over a long period often until the temperature has again subsided.

Hiccough may occur as an intoxication due to chronic nephritis, associated with uremia; in diabetes, gout, and alcoholism. In chronic nephritis this symptom is ordinarily associated with a high blood nitrogen and urea, pointing to its toxic origin. In diabetes and gout the blood chemistry, too, gives evidence of a serious toxemia.

4. *Affection of the Thoracic Viscera.*—Among the affections of the thoracic vicera in which hiccough may occur, the following are most important; bronchial asthma, diaphragmatic pleurisy, empyema, gangrene of the lungs, pericarditis, tumors of the chest. It may occur in any of these affections due to an irritation of the pneumogastric, in addition to the toxemia occasioned by the individual disease. In pericarditis it is a significant sign of an impending fatal outcome; in chest tumors it is frequent, and is directly due to pressure along the phrenic nerve or at its origin.

5. *Affections of the Abdomen.*—Hiccough occurs in many affections of the gastrointestinal tract, in gastritis, gastric atony, dilatation, carcinoma, amebic dysentery, enterocolitis, intestinal obstruction, appendicitis, pancreatitis, hepatitis, cholecystitis, peritonitis, and following operative procedure on the gastrointestinal tract.

In atony and dilatation, it is usually due to the distention of the stomach, and is therefore frequently relieved by lavage. In carcinoma of the stomach, involving the pylorus, it is likewise due to distention, while in carcinoma of the cardia and body of the stomach, it is caused by the proximity of this affection to the diaphragm and reflex irritation of the splanchnic plexes. In amebic dysentery and enterocolitis it occurs in the grave forms before death, when the peritoneum is involved. It is not uncommon in the last stages of intestinal obstruction as well as in cases of strangulated hernia in which operation has been too long delayed.

It occurs in cases of acute perforative appendicitis, suppurative pancreatitis and perihepatitis, serious gallbladder infections and peritonitis, due to the involvement of the lower surface of the diaphragm in which affections the hiccough becomes extremely aggravated and persistent, usually with fatal termination.

Hiccough may be an alarming symptom following abdominal operations. It occurs not infrequently after manipulation of the upper abdominal organs, such as in operations on the gallbladder and stomach, coming on immediately and gradually subsiding after a few days. In the more serious forms, due to infections and consequent peritonitis, it usually appears later; that is, after a few days becoming more and more intense and persistent and denoting a fatal outcome.

Kuttner has reported twelve cases of hiccough following operations. In this entire series, the occurrence of this symptom was noted within a few hours following the operation. The type of operation or anesthetic used apparently had no influence as a causative factor. Frequently the condition became so severe as to become an alarming complication. Of the twelve cases reported, four were in operations on the genitourinary system; eleven of these patients were males.

6. *Cerebrospinal and Other Organic Nervous Affections.*—Hiccough occurs in many organic nervous affections. It has been observed in cases of brain tumor of the posterior cranial fossa, lesions of the cord, epilepsy, meningitis, and as the crisis in tabes dorsalis (probably due to direct irritation of the ninth and tenth nuclei in the medulla) and in epidemic lethargic encephalitis, hydrocephalus, etc. It has been stated that under rare conditions, an attack of hiccough may replace, as an equivalent state, the usual epileptic seizure.

SYMPTOMATOLOGY

The symptomatology of singultus varies with the causation and severity of this affection. As has been pointed out, when the affection is moderate, appearing at intervals of every ten or twenty seconds, sufficient time elapses for the respirations to proceed easily and deglutition, too, is not impeded. When the hiccough, however, proceeds in rapid succession and continues for long periods, both day and night, exhaustion is rapidly brought about and with it signs of an impending fatal outcome. With the exhaustion, discomfort and pain arise in the lower portion of the chest, and in addition, headache, thirst, acceleration and weakness of the pulse, are not uncommonly noted. The patient now finds himself much debilitated, extremely nervous, and not infrequently with a fear of impending danger to life.

TREATMENT

At times, depending upon the severity of the condition, the simplest measures will overcome an attack of hiccoughs, while in other instances, none of our known remedies will exert the slightest influence. These simple remedies consist of sipping water, taking deep inspirations at regular intervals, or in exciting sneezing as by means of snuff or tickling the nares or the throat, causing vomiting; or in forcible traction on the tongue; or by a sudden shock, produced unawares to the patient; sipping bits of crushed ice; pressure on the back of the neck; hypodermic injection of adrenalin chloride, 1 in 1,000; inhalation of amyl nitrite or ammonia; the ice bag or a mustard plaster to the epigastrium; lavage of the stomach; galvanism over the cervical area, etc.

In the more aggravated forms it is important as far as possible to determine the cause of the affection; relief frequently being afforded by overcoming this factor. If this is occasioned by dietetic indiscretions the stomach should be emptied by means of emetics, or better by lavage. Careful dietetic regulations should be insisted on and the various gastrointestinal disturbances as far as they bear a causative relation to this condition, should be relieved by means of appropriate treatment.

In many instances benefit is derived from lavage of the stomach with an alkaline solution; in other instances purgatives of various forms give relief. The following remedies have at times been found of value: tincture of capsicum, Hoffman's anodyne, tincture of valerian, bromides and chloral, tincture of musk and oil of amber, cocaine, anesthesin, chloretone, belladonna or atropine and validol.

Of special value according to our experience is the remedy recommended in recent years by Macht known as benzyl benzoate. Inasmuch as this drug exerts its chief effect peripherally on the smooth muscle structures, it is most useful in the treatment of hiccoughs of probable peripheral origin. It should be administered in doses of from forty to sixty drops, well diluted, at two or three hour intervals. In renal disease, the usual associated uremia must be especially treated by means of hot packs and baths; pilocarpine or jaborandi.

In serious and persistent singultus, especially those forms complicating acute peritonitis, pancreatitis and following abdominal operations, opiates in the form of morphine or pantopon administered hypodermically and inhalations of chloroform are to be recommended early as a means of affording at least a certain degree of temporary relief.

In certain aggravated cases under our care, direct galvanization to the neck was the only means of obtaining relief. Recently D'Alessandro described a method which he has employed with much success. The left carotid sheath is grasped by the thumb and forefinger, at the anterior border and midway between the origin and insertion of the sternocleidomastoid muscle. The sheath is compressed tightly for about one minute and the hiccough usually ceases immediately.

CONCLUSIONS

1. Hiccough is a symptom varying in intensity from a slight form to an extremely grave type, which may terminate in death.

2. It is important in the proper treatment of this affection to determine its cause as far as possible, which, however, may be extremely difficult in many instances.

3. Numerous remedies are recommended in the treatment of this affection, but are so uncertain that it is frequently necessary to take advantage of the various forms, one after the other, in the hope of obtaining a cure.

Six Deaths Following Fumigation with Hydrogen Cyanide

WILLIAM D. McNALLY, M.D.,
Chicago, Ill.,
Chemist to Cook County Coroner's Laboratory

Hydrogen cyanide or prussic acid generated by the action of an acid upon sodium cyanide has been used in the United States since 1886 as an insecticide with but few accidents (1). It is a deadly poison especially in the hands of an individual not fully aware of the danger of its use, or lacking intelligence and skill to guard against accidents.

The more extended use of this poison in the last year for the destruction of pests is responsible for the increasing number of deaths by this agency. The seriousness of the situation is forcibly brought to our attention in the report of six deaths during one fumigation. Unless a community has had a similar tragedy such as the one that occurred in Chicago, and passed regulations to safeguard its people against such accidents, deaths will continue to be reported by this dangerous method of fumigation.

On the night of March 3, 1923, the proprietors of a restaurant in South Chicago turned over their restaurant to a man engaged in the extermination of pests to have the roaches destroyed by him. Above this restaurant were two flats. The people in these flats were warned in a perfunctory manner by the fumigator that he was going to fumigate the restaurant below and to leave their windows open. The spaces around the water and steam pipes entering the ceiling were sealed with paper. A shaft two feet by six inches leading to the flats above was not properly sealed and the gas being generated entered the first and second flats above. The materials used in the fumigation process and their proportions were these recommended in a Farmers' Bulletin of the Department of Agriculture (2).

Sodium cyanide	1 oz.
Sulphuric acid	1½ oz.
Water	3 oz.

For each 100 cubic feet of space to be fumigated earthen jars or crocks having a capacity of about two gallons were used as generators. The water was added to the jars and the required amount of acid afterward to avoid spattering, which would occur in the reverse order. After the required number of jars were prepared, paper bags containing the cyanide were dropped into the dilute acid. The fumigator sealed the front door of the restaurant and put a sign on the door warning the public not to enter. At 9 a. m. the next morning one of the owners opened the front door. The gas was so strong that

he was forced to leave and was under a physician's care for two days. At 10 a. m. a roomer in the flat above who had slept in a front room with his window wide open found one of the occupants dead in the bath room. A physician was called who notified the police, who in turn found the bodies of five more people. The police noted a peculiar odor upon entering the flat. The bodies of all the victims had the natural color and resembled those in deep sleep. The dependent parts of all were of a light red. Three hours after the bodies were discovered the peculiar peach kernel odor of hydrocyanic acid was detected coming from the open mouths of the victims. Lividity and rigor mortis were marked in all six cases.

A postmortem examination was made upon only one of the bodies, H. S., aged fifteen years. Upon opening the body the odor of hydrocyanic acid was marked in the thoracic cavity. The right ventricle was full of dark fluid blood. The lungs, liver, kidneys and spleen were highly congested. The stomach and bowels did not show anything abnormal. The lungs, kidneys, liver, stomach, bowels, and a specimen of blood were removed for chemical examination. This examination, made eighteen hours after the postmortem, gave a positive Shönbein test for cyanide but failed to give the thiocyanate and Prussian blue tests.

The people in the adjoining flat and the flat above had their windows open and escaped being asphyxiated. In the flat above where the accident occurred the people noted the odor of the gas and opened their windows and escaped being poisoned. Four gold fish in a bowl of water in one of the rooms were killed by the absorption of the acid fumes. (Milk and other liquid food also absorb hydrocyanic acid and should be removed before fumigation.)

The use of hydrocyanic acid as an agency for disinfestation of dwellings should be forbidden by the health authorities. If its use is permitted the dangerous nature of the gas must be communicated to the owners and tenants of the building. The building must be vacated and fumigation performed by an intelligent person who understands the necessary safeguards against accident.

Radiological Findings in a Case of Echinococcus Cyst of the Lung and the Liver*

I. GLASSMAN, M.D.,
New York

Case.—P. M., Serbian, female, aged thirty. Admitted to the Volunteer Hospital January 9, 1922. Her mother and father were reported as well. There was no history of family diseases. There had been no diseases of childhood. The surgical and menstrual histories were negative.

Eight months ago the patient began to complain of belching, nausea, and vomiting after meals. Later pain developed in the right side of the abdomen, which was dull in character and more or less continuous. There was no relation of the pain to eating. The appetite was good, bowels constipated, urination normal. There was no loss of weight.

The patient was well nourished, and did not appear acutely ill. The abdomen, on palpation, presented a mass in the right upper hypochondriac region below the costal margin. The mass was smooth and tender on palpation and moved with respiration. The pulse was 70, temperature 98° F. on admission. The urine was straw yellow, specific gravity 1.025, with a heavy trace of albumin. Microscopic examination showed numerous pus cells, epithelial cells and mucus. Pain in the abdomen, gastric distress, nausea, belching and vomiting were the chief complaints. A clinical diagnosis of hydrops of the gallbladder was made.

The patient was referred for radiological examination of the gastrointestinal tract and gallbladder region on January 11, 1922. Examination of the gastrointestinal tract revealed no evidence of any pathological condition. Examination of the gallbladder revealed a mass in the right hypochondriac region, extending downward, below the free border of the right lobe of the liver for about four inches, covering the right kidney. It was smooth and sharply circumscribed and had the same density as the liver substance. The same shadow repeated itself on the gastric plates. A diagnosis of cyst of the liver was made.

The patient was operated upon on Jan. 17, 1922. A transverse incision in the right hypochondriac region was made. There was no free fluid found in the peritoneal cavity. A large cyst the size of a grapefruit originating in the liver and protruding downwards was discovered. The cyst was pearly grey in color, soft in consistency and fluctuating. The cyst was opened and clear greyish fluid was found. The contents of the cyst, besides the fluid, consisted of numerous pieces of greyish tissue, which were thought to be daughter cysts. After evacuation the cyst was removed. Another cyst, smaller in size, was treated in the same manner. A third cyst was found in the left lobe of the liver, but excision of the latter was thought inadvisable. It was then packed with gauze and a drain put in place.

The parent cyst contained a number of daughter and granddaughter cysts. Extending from the inner wall of the cyst there were little fat granules, which eventually developed into scolices, which represented the head of the tænia echinococcus. The outgrowth examined under the microscope was found to contain four sucking discs and a circle of hooklets. One of

*Read before the Harlem Medical Society, May 3, 1922.

the cysts was multilocular containing loose bodies surrounding a capsule of connective tissue.

When infection takes place from a hog or dog, the embryo freed from the egg shell burrows through the wall of the intestine. On reaching the peritoneal cavity it enters the portal circulation and is carried

FIG. 1.—The semilunar shadow in the right hypochondriac region is the protruding echinococcus cyst of the liver.

to the liver. On entering the systemic circulation, it passes to the pulmonary capillaries. On reaching the liver or the lung the hooklets disappear and the small embryo is gradually converted into a small cyst, which is two distinct layers—external laminated, which is the capsule proper—and the internal paren-

FIG. 2.—Shadow of the echinococcus cyst of the liver.

chymatous layer. These are gradually converted into cysts, having the same structure as the mother cyst. A section of the endocyst was made and found to be typical of the daughter echinocccus cyst. The patient died on January 18, 1922.

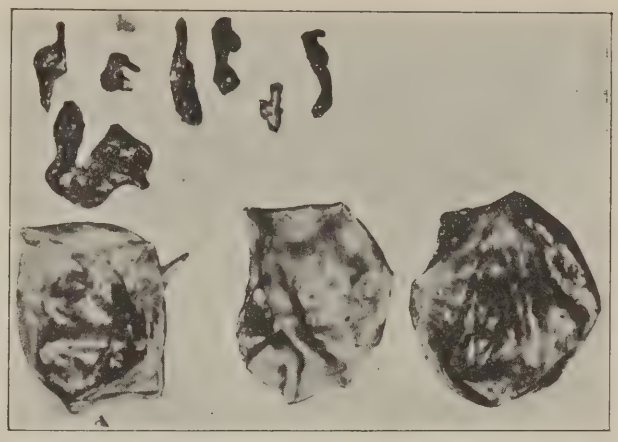

FIG. 3.—Mother and daughter cysts excised from the liver.

FIG. 4.—Lung showing three large echinococcus cysts.

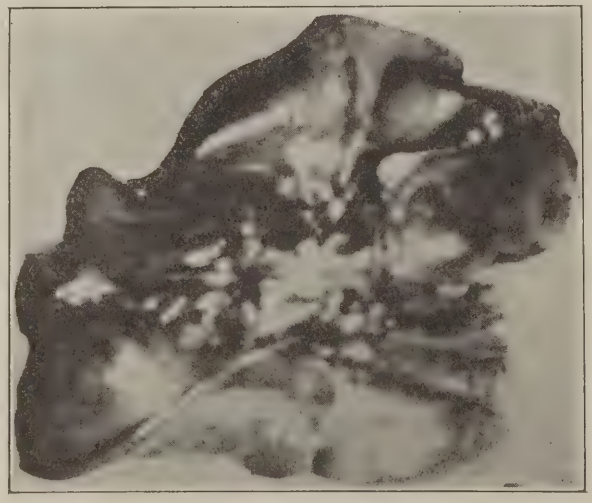

FIG. 5.—Posterior view of the lung.

AUTOPSY REPORT.

The peritoneum was found to be smooth and uninjected. There was about a pint of blood stained fluid. The intestines were moderately filled with gas. The free edge of the liver was at the tenth rib. There was no evidence of thrombosis in any of the large bloodvessels. The liver was perfectly free with a gauze drain leading from the abdominal wound to the under surface of the liver. The gallbladder was normal and moderately filled with secretion. The liver showed cystic areas and one cyst on the left lobe of the liver. Surrounding the areas of the cyst removed at the operation, there were a number of hemorrhagic spots and a few areas of brown atrophy. The three cysts occupied almost a third of the area of liver tissue. A cut section of the liver showed a nutmeg liver with brown atrophy. The spleen was soft and normal in size. The right kidney was freely movable and displaced downwards. The pelvis of the kidney contained pus. The kidney was smaller than usual, the capsule peeling easily. The left kidney was apparently normal.

The lung showed two cysts in the right lower lobe and one cyst in the left upper lobe. These were similar to those found in the liver and occupied two thirds of the pulmonic field.

In this case the clinical picture was confusing. The x ray examination of the chest was not done prior to the examination, because it was not requested. The diagnosis in this case would have been comparatively easy with a radiographic plate of the lung. In spite of the negative clinical findings of the lungs, the x ray examination and the findings of the multiple cysts of the lungs, together with the suspicious shadow at the right lobe of the liver, would have made the diagnosis of echinococcus cyst comparatively simple.

The only time when clinical diagnosis of echinococcus cyst of the lung is possible, is when these perforate into a bronchus, the patient coughing and expectorating the scolices and daughter cysts. There was no cough or expectoration in this case. Therefore it is obvious that in every abdominal condition, where an x ray examination is required, the internist as well as the surgeon should insist on a routine examination of the chest.

Conditions other than those mentioned, such as Hodgkin's disease, lymphatic leucemia, abdominal cancer, with metastasis, make their early appearance in the lung, before the typical clinical symptoms manifest themselves.

182 Lexington Avenue.

Diagnosis of Occlusion of Posterior Inferior Cerebellar Artery*

ALFRED GORDON, M.D.,
Philadelphia

Occlusion of the posterior inferior cerebellar artery is not a frequent occurrence. Its diagnosis depends upon a critical analysis of the clinical symptoms. Since occlusion of the vertebral artery, of which the cerebellar is a branch, may give similar manifestations, it is to be borne in mind that there are nevertheless additional symptoms depending on a wider distribution of the latter bloodvessels. In view of this fact and before presenting a description of a case which has the fundamental characteristics of this affection, it would not be superfluous to recall the anatomical facts concerning the origin and distribution of this artery.

Each of the two vertebral arteries gives off a posterior inferior cerebellar artery at about two cm. below their union into the basilar trunk. Slightly above it the anterior spinal artery originates. The latter descends along the anterior median fissure of the medulla oblongata and sends branches into the interolivary bundles, posterior longitudinal bundles, nucleus of the twelfth nerve, and other nuclei below the fourth ventricle, also into the pyramids. The posterior inferior cerebellar artery passes between the roots of the twelfth and the eleventh and tenth, then bends at a right angle backward and runs between the medulla and the cerebellar hemisphere; then divides into a mesial and a lateral branch. The mesial supplies the mesial part of the hemisphere and the inferior vermis. The lateral branch supplies the inferior surface of the cerebellar hemisphere as well as the superior surface after its anastomosis with the superior cerebellar artery, but the trunk of the inferior cerebellar artery gives off branches to the medulla. It is therefore evident that when the anterior spinal arteries are occluded, symptoms referable to the central and anterior parts of the bulb will be present, but when the posterior inferior cerebellar artery is occluded, symptoms referable to the lateral portion of the medulla oblongata will be conspicuous.

While this distinct distribution of the two branches is common, nevertheless it should be borne in mind that there may be variations in distribution of the vertebral arteries, since the latter in some cases have been found to supply the lateral and the posterior part of the medulla like the posterior inferior cerebellar artery itself. Such a case is reported by Breuer and Marburg (1). However, in the few exceptional cases recorded, in addition to the symptoms of occluded posterior inferior cerebellar artery, there were other symptoms.

For a proper and correct diagnosis in cases of this kind, the anatomical arrangements of the nuclei of the cranial nerves, the pathways of the latter, the relative position of the first, and the distribution and direction of various tracts, the function of the latter should be taken into consideration. A careful discrimination of the clinical symptoms in the minutest details will enable one to arrive at a localizing diagnosis.

If we turn our attention to the clinical picture of occlusion of the posterior inferior cerebellar artery,

*Paper read and patient exhibited at the meeting of the Philadelphia Neurological Society, October 27, 1922.

judging from its distribution in the medulla we find that while there may be many variations, nevertheless the outstanding symptoms, common to all cases, are as follows: Sudden onset; motor disturbances on the same side in the form of ataxia and asynergy; sensory disturbances on the opposite side and of the syringomyelic type; symptoms referable to the glossopharyngeal and vagus nerves, such as difficulty of deglutition, impaired sensibility of the pharynx, paralysis of the soft palate and larynx; symptoms of involvement of the facial nerve on the side of the lesion; symptoms of involvement of the sympathetic nerve (narrowness of the palpebral fissure and of pupil, also retraction of the pupil).

An analysis of the cases put on record shows considerable variability in the number of the symptoms mentioned and in their intensity, also in the presence of additional disturbances. For example, in Leyden's case, in which a focus of softening was found in the right half of the medulla there were no objective sensory disturbances (2). In Hun's case, one of the softened areas was in the left side of the medulla. Analgesia and thermoanesthesia were present in the left side of the face and right side of the body. Ataxia was present on the side of the lesion. There was a tendency to fall toward the left and the head was inclined to the same side (3). In Muller's cases, the symptoms were: Dysphagia, paralysis on the side of the lesion of the soft palate, larynx and sympathetic supply; weakness of the corneal reflex; sensory dissociation on the left side of the body and over the first branch of the fifth nerve in the face; vesical symptoms; intense headache; priapism; glycosuria and albuminuria (for a short time). There were no motor symptoms in the extremities.

Eisenlohr and Lichtheim (4) consider as characteristic of occlusion of posterior inferior cerebellar artery sudden loss of speech, of movements of lips, tongue, paralysis of the larynx and of the limbs on one side. However, these symptoms were not present in every case, such as in Spiller's (5). The reflexes are absent or lost in some cases and exaggerated in others. In Rossolimo's cases, they were diminished (6); in Senator's case, they were lost (7); in Hun's case, exaggerated on one side; in Spiller's case, abolished, and increased in Anderson's case (8). Sympathetic phenomena are not present in every case, although as a rule they are frequent. Paralysis of the soft palate may be bilateral. Disturbance of speech, although frequent, is not constant. Subjective sensory disturbances are common, but again not constant. Objective sensory disturbances of the syringomyelic type are frequent. In Senator's case, however, also the tactile sense was impaired (9). In Spiller's case, the sensations were preserved.

The involvement of sensations over the area of distribution of the fifth nerve may be confined to one or more of its branches on the side of the lesion or on the opposite side, depending upon whether the involvement was in the spinal root or in the central tract of the fifth nerve after the fibres have decussated (10).

The enormous variations in the symptomatology are evidently due, judging from the pathological reports, to the difference in the precise localization of the lesion and its extent. Although in the majority of cases the number of symptoms is large, there are cases which are unaccompanied by widespread clinical features, but in which, nevertheless, the symptoms present are so persistent and conspicuous that an error of diagnosis may be avoided. Such a case is submitted here.

Case I.—Patient S. S., male, aged thirty-six, automobile repairer, about three months ago, while getting off a car, saw himself running towards the left side, but he did not fall. This lasted a few minutes. Several days later severe headache developed suddenly in the right temporoparietal region, which lasted several hours. There was no vomiting or dizziness. The next morning he felt very weak and could not go to work. The headache reappeared on the same side and was accompanied by vertigo. Both lasted five to ten minutes. This was followed immediately by difficulty in swallowing and awkwardness in the left upper limb.

At the end of five weeks he presented the following condition: Gait and station, with open and closed eyes, normal; station on either foot, normal; movements of individual extremities, correct; grip of either hand, normal. The head seemed to be slightly tilted to the right, and the face slightly deviated to the left, the left nasolabial fold being somewhat deeper than the right. The right orbital fissure appeared to be wider than the left. The pupils were equal and reacted to light, but the right responded more sluggishly than the left. The ocular muscles were normal, also the fundi oculi.

There was no ataxia in the upper extremities, no adiadochokinesia, and no tremor. Pointing with eyes closed was correct with either hand. The knee jerks were markedly increased, there was no ankle clonus on either side, and the plantar reflex was of flexor type by any of the methods.

Sensations were altered on the left side in the face, neck, thorax, dorsum, shoulder, arm and hand. The sense of touch was normal and equal on both sides, but pain and temperature perceptions were considerably diminished. Cold was in some areas taken for warm, and hot was in some places not recognized at all. The region thus involved occupied the area of distribution of the second and third branches of the fifth nerve on the face; on the thorax and dorsum only as far down as the mammillary line. Immediately below this line the sensations were normal. On the arm the sensory dissociation was present on all its aspects. The deep sensibility on the left side was not involved, since position, pressure, stereognostic sense, etc., were all intact.

Another conspicuous symptom was the inability to swallow liquid or solid food, so that the patient had to be fed through a nasal tube. The soft palate and uvula were drawn somewhat to the left. The epiglottis and entire larynx also appeared drawn to the left. The vocal cords functionated normally; there was no hoarseness, the voice was clear. Sensations over the right side of the soft palate and uvula were greatly diminished. The sense of taste in the mouth was normal, the motor and sensory apparatus of the tongue intact. Smell in either nostril was normal. The patient was much disturbed by accumulation of mucus in the throat and was obliged to expectorate frequently. Hearing was normal on both sides. A vestibular test showed loss of function of

the vestibuloocular as well as of the vestibulocerebellocerebral pathway from the vertical semicircular canals of both sides. The horizontal canal pathway appeared to be unaffected. There were no other abnormal symptoms; Wassermann reaction of blood and spinal fluid normal; mentality good; urinanalysis, negative. There were no evidences of a focal infection. The heart was somewhat enlarged and a mild presystolic murmur could be heard at the base.

Repeated examinations of the patient gave invariably the same results. Only a few days ago some modifications were observed for the first time. The syringomyelic sensory dissociation described above became less marked on the left side of the face. The area of distribution of the second and third branches of the left trigeminus became less affected: instead of complete loss of pain and temperature perceptions, there was merely a slight diminution of these two sensibilities and the real loss of sensations commenced at the lower border of the mandibula. Moreover, the deviation of the face to the left was less marked than before. The secretion and accumulation of secretions in the pharynx had also diminished.

Lately the patient observed that small quantities of fluid passed down the esophagus without much difficulty. The deglutition therefore commenced to improve. With the continuous amelioration of the original condition a new symptom developed, viz., paresthesia in the left arm. Grasping it or applying a cold object to it provokes intolerable pain, There is, however, no suffering whatever when the arm is not touched.

Analysis of the symptoms in this case shows an analogy with many other cases of the same character. We find here a sudden onset with vertigo and ataxia, lasting but a few minutes and indicating a partial occlusion of the artery. As the occlusion kept on increasing and the thrombus became larger so as to narrow the lumen of the bloodvessel to a great extent, vertigo and pain in the right temporal region made their appearance again. When the occlusion became complete, the conspicuous symptoms set in. First of all, the difficulty and finally the inability to swallow, the difficulty of clearing the throat of phlegm, together with the unilateral paralysis and anesthesia of the pharyngeal muscles of the soft palate and of the uvula, indicate an involvement of nuclei of the glossopharyngeal and pneumogastric nerves. The nuclei of these two nerves are three in number: one is the nucleus alæ cinereæ, which is the terminal nucleus of the sensory portion of the tenth nerve. Most of the sensory fibres of the nerve end in this nucleus, but some descend, forming a part of a small bundle dorsal and lateral to the nucleus of the ala cinerea, namely, the solitary bundle. The nucleus of this bundle, together with the ala cinerea, is common to both the ninth and tenth nerves. The solitary bundle contains more fibres of the ninth than of the tenth. Both are mixed nerves. The sensory fibres end in the above mentioned nuclei, but their motor portions originate in the nucleus ambiguus, which is situated midway between the olive and the gelatinous substance. Its axons take a dorsolateral route and join the sensory fibres. The forward continuation of the nucleus ambiguus constitutes the nucleus of origin of the seventh cranial nerve (3).

We are thus in a position now to localize the lesion in the medulla at least for the nuclei of the tenth, ninth and seventh nerves, since they were all more or less involved in our case, which is seen from the difficulty of deglutition, paralysis and anesthesia of the soft palate, uvula and pharynx, also from the slight facial paralysis on the right side.

In the vicinity of these nuclei lies the gelatinous substance embraced by the spinal tract of the trigeminal nerve. The fibres of the fifth nerve possess distinct functions and those conveying impulses for thermic and algesic perceptions are gathered in the descending root of the fifth nerve. The involvement of these descending fibres explains the sensory dissociation observed in the lower part of the face, namely, in the domain of the second and third branches of the fifth nerve. Since the sense of touch on the face was preserved but the sense of pain and temperature disturbed, one is justified in assuming that they are separate tracts and the former succeeded in this case to escape. Moreover the existence of a sensory disorder in the area of the second branch indicates this fact that the lower part of the medulla is involved, which corresponds to the other localizations mentioned above.

The examination of the vestibular apparatus has shown that the vestibulocerebellar pathway from the horizontal canal is not involved but the pathway from the vertical semicircular canals is affected. Since the connections from the horizontal canal through the inferior cerebellar peduncles are not involved, vertigo and ataxia could not be expected. This is precisely the situation in our case. With the exception of the onset of the disease, when a sudden vertigo occurred, the patient has been totally free from it during the entire course.

The sympathetic syndrome, which is frequently present in cases of occlusion of the posterior inferior cerebellar artery or of the vertebral artery or of both, has been conspicuously absent in the present case from the time the disorder made its first appearance. Evidently the sympathetic fibres, which are located in the medulla in the dorsolateral portion of the reticular substance, escaped in spite of their close proximity to those of pain and temperature or to the descending root of the fifth nerve.

It was mentioned above that the temperature and pain sense were altered in the face on the opposite side. The lesion was presumed to enclose the spinal root of the left fifth nerve in the area of distribution of its second branch. The analgesia and thermic anesthesia over the neck, the thorax down to the mammillary line, over the dorsum down to the same level, over the shoulder, arm, forearm and hand on all their aspects, have a different localization than those of the face. Here the tactile perception was entirely preserved showing the integrity of the median lemniscus, but the fibres of Gower's tract are evidently interrupted. This pathway lies in the most lateral portion of the lower part of the medulla in the formatioreticularis. The fibres of the tract have a contralateral function because of their continuous decussation at successive levels in the median plane of the spinal cord (1). Here, as in the case of the face, it is highly probable that the tactile pathway follows a different direction than the thermal and algesic tracks. Gower's tract at the level of the

medulla under discussion lies close to the gelatinous substance of Rolando, which is the nucleus of the descending fibres of the fifth nerve. Both portions are included in the affected area. The latter consequently embraces the nucleus of the ala cinerea, the nucleus of the solitary bundle, the nucleus ambiguus, the nucleus of the descending root of the fifth nerve, finally Gower's tract. Presently the occluded branch of the posterior inferior cerebellar artery is gradually getting rid of its thrombus and its lumen is becoming free.

The progressive improvement in swallowing, in the function of the uvula and of the soft palate, and finally in the sensory disorder, speak in favor of the reopening of the bloodvessel. Gillis's statement as to the disappearance of all the symptoms in the course of two to six months with the exception of the sensory disorder (11) is partly in conformity with the condition of the present case. Here all the manifestations show a simultaneous improvement: not only the deglutition but also the sensory dissociation is gradually disappearing.

The diagnosis of occlusion of the posterior inferior cerebellar artery presents no special difficulty if its exact anatomical distribution is taken into consideration. A correct knowledge of localization of various nuclei and tracts in the medulla at its various levels is indispensable. Although, according to Salmon (12), the symptomatology is analogous to that of occlusion of the vertebral artery, although in many instances both bloodvessels were found to be involved, nevertheless a careful analysis of the clinical symptoms will enable one to make a pretty accurate discrimination of what symptoms belong to occlusion of one or the other vessel. By reason of its larger distribution, namely, over a larger area of brain tissue (see above), the symptomatology will naturally be richer than in cases where only one of its branches is involved, such as, for example, the posterior inferior cerebellar artery, the area of distribution of which is limited. Wallenberg's statement (13) should be taken into consideration as it has proven to be correct in many instances. He said that when the difficulty of deglutition is persistent, both the vertebral and the posterior inferior cerebellar artery are involved, whereas a transient paralysis is caused by an obstruction of the latter artery alone. Wernicke observed that pathological foci in the lateral field of the medulla are always due to an occlusion of the posterior inferior cerebellar artery (14). The case recorded here apparently justifies such an assumption, its limited symptomatology is corroborative of the above statement. The case is also instructive from the diagnostic viewpoint that, contrary to the majority of similar cases, the morbid manifestations are here very small in number and so distinct and clear cut that not only no error can be committed as to the diagnosis, but an exact localization of the lesion can be figured out in the medulla and at its exact level.

As to the nature of the lesion, it is very probably vascular. According to Salmon *(loc. cit.)*, eighty-eight per cent. occur in alcoholics and syphilitics. Although in the present case the Wassermann reaction was negative in the blood and spinal fluid, nevertheless antiluetic treatment was instituted (neoarsphenamin, etc.), with apparently satisfactory results. The patient has a cardiac lesion which is a sufficient cause to produce an embolic or thrombotic occlusion of an artery.

The localizing diagnosis in such cases must be based upon an accurate estimate of the clinical manifestations in their relation to the function of the various constituents of the medulla.

Pachymeningitis Hemorrhagica Interna

*Report of a Case of Nontraumatic Spinal Fluid**

By HERMAN FRIED, M.D.,
New York.

The first case found in the literature which corresponds to the symptoms now recognized as pachymeningitis hemorrhagica interna was described by Ambroise Paré, and was that of Henry II., who was fatally wounded in a tourney in 1559. Blood was found between the membranes, postmortem. In 1819, Serres separated cerebral and meningeal hemorrhage, although credit for this work has been attributed also to Morgagni. Cruveilhier, in 1829, established a theory in regard to the pathology of this condition, which was supported by Virchow (1) and was described at length by the latter in 1857. These men noted the inflammatory nature of the membranes on the inner surface of the dura, believing it to be a primary condition which precedes the resultant hemorrhage. Much controversy has since ensued in regard to this theory which, however, seems to be supported by the majority of writers. The opposite view—that hemorrhage is the primary condition and the organization of the clot is respon-

*Case presented at the Yorkville Medical Society, December 19, 1922.

sible for the membrane formation—was first held by Huguenin (2). Even at the present time the question as to the pathogenesis is still an open one, each theory having its various advocates.

Pachymeningitis hemorrhagica interna, also known as hematoma of the dura mater, is a comparatively rare form of pachymeningitis, attacking males more frequently than females. It is particularly rare in infancy, but more frequent during the first year of life than between the first and twenty-first years. Blackburn (3) in a study of 374 cases, found it only in one instance in persons under twenty years of age, and in six cases under thirty years. The great majority of cases were in patients well advanced in years. Of these 374 patients, 110 were over seventy years; one hundred were between sixty and sixty-nine years; eighty-two were between fifty and fifty-nine years; fifty-one cases occurred between forty and forty-nine years; and twenty-five in persons between thirty and thirty-nine years of age. According to this writer, statistics show that this condition is more frequent among the aged insane, in paresis, and in epileptics, and although it cannot be considered as characteristic of any special form of mental disorder, it seems to be more common in general paralysis and epileptic insanity.

The condition is attributed to many and varied causes. It occurs generally in adults suffering from progressive paralysis, senile dementia, hemorrhagic diathesis, arteriosclerosis, brain tumors, alcoholism, lead poisoning, syphilis, severe anemia, tuberculosis, and as a result of traumatism and sunstroke.

Pachymeningitis hemorrhagica interna in infancy, according to Schwartz (4) is probably an infectious disease and may, in all likelihood, be traced to the meningococcus. He believes pachymeningitis and leptomeningitis to be different manifestations of the same organism, namely the meningococcus. Further, that since there are various forms of meningitis produced by various organisms, it seems likely that similar divisions might occur among cases of pachymeningitis. To substantiate his theory, he refers to two cases in children, one reported by Rosenberg (5), in which streptococci were isolated, and another reported by Dupéné and Dubourg (6), in which tuberculous meningitis and pachymeningitis were present in the same case. Whether the same form of the disease is found in adults as in infants, and whether the theory of infection is identical in both is still to be proved. Bulging of the fontanelle is considered one of the most significant features in cases of children.

The symptoms do not always form a precise clinical picture, and for this reason the diagnosis may present the greatest difficulty. In fact, Bramwell (7), Jelliffe and White (8), Elsner (9), Spear (10), Blackburn (11), and others admit that the condition is rarely recognized during life. Very recently, however, Arthur D. Dunn (12) has published a report of five cases of internal hemorrhagic meningitis, in which he pointed out the uniformity of the clinical picture they represent. He defined and described a group of symptoms pathognomonic of this disease, making it possible for every physician to recognize the condition. The fact that the course of the symptoms depends upon the situation and extent of the morbid process must always be kept in mind.

The onset is always sudden, ushered in with severe and almost unbearable headache, usually located in the occipital and basal regions and in the neck. Associated with headache are found vomiting, rise in temperature, convulsions, a relatively slow pulse rate and more or less stupor. Evidences of meningeal and spinal nerve root irritation soon develop. These include hyperesthesia, deep muscle tenderness, tenderness along the spine, muscular rigidity and Kernig's sign. Probably the most important diagnostic sign is furnished as a result of lumbar puncture, which shows a bloody spinal fluid containing well formed red blood cells giving negative smears and sterile cultures, together with a strong albumin and globulin reaction. A striking feature of the disease is the reappearance of fresh blood in the spinal fluid following every insult or exacerbation of symptoms such as headache and convulsions. This phenomenon is peculiar to internal hemorrhagic pachymeningitis.

Regarding the secondary symptoms, Dunn says: "Symptoms of irritation or destruction of the upper motor or sensory neurons such as paralyses, pareses, convulsions, Jacksonian epilepsy, exaggerated tendon reflexes, disturbed superficial reflexes (positive Babinski, Oppenheim, absent abdominal reflexes, etc.) disturbed psyche and sensorium, are merely phenomena which mirror the localization and severity of the process. The absence of residual paralyses is noteworthy. Choked disc and retinal hemorrhages are frequently noted in the literature. They were absent in our cases, which was probably due to the fact that all of our cases save one were punctured within twelve hours of the onset, and that subsequently the intracranial pressure was not allowed to increase much beyond the normal in so far as it could be reduced by repeated lumbar punctures."

In my case presented below, the absence of choked disc and retinal hemorrhages were also noted, in spite of the fact that there was an unavoidable delay of three days in performing the first lumbar puncture. Although the second puncture followed closely upon the onset of the recurring symptoms, there was no variation in the results obtained. According to our findings it would therefore appear that Dunn's theory regarding the influence on intracranial pressure as affected by the difference in time between the onset of the attack and the administration of lumbar puncture has not been borne out in the present instance.

CASE.—Patient, a man of fifty-eight years, first seen June 7, 1922. His family history, particularly as to blood diseases, hemophilia, cerebral hemorrhage or tumor of the brain revealed nothing of importance. Patient had always enjoyed excellent health, could not recall any illness since infancy or childhood. Habits had been good and regular, except that he had always been a heavy beer drinker. No history of trauma.

Onset came suddenly, with intense headache, vomiting and a convulsion. For the next forty-eight hours he lapsed into a stupor, with severe pains in his muscles, cramps, and paravertebral tenderness. Muscular pains were so severe that the patient cried out when he moved about. There was a febrile reaction of 102 degrees; pulse 80. His head was drawn backward; neck rigid; Kernig's sign was present; absence of patellar reflexes. Suggestions of Babinski and Oppenheim's signs were obtained about the

third or fourth day after onset. Fundi were reported normal by an ophthalmologist, but patient showed conjugate deviation to the left; no other eye symptoms or disturbances of ocular muscles. Pupils and pupillary reflexes normal. At no time did patient complain of diplopia. There was no ptosis. Leucocyte count 12,000. Urine: specific gravity 1,022; showed albumin, hyaline and granular casts, no sugar. Systolic blood pressure 180.

Lumbar puncture had to be delayed for two days, owing to certain objections of family and friends. On June 10th—three days after onset, and about ten hours after the second convulsion—lumbar puncture was performed by Dr. Emanuel Appelbaum and myself and twenty-five c. c. spinal fluid were obtained under increased pressure. Examination showed a bloody or orange yellow fluid with blood sediments. Cytology was not performed, owing to the presence of red blood cells. Bacteriological examinations of smear and culture, after twenty-four, forty-eight and seventy-two hours, were negative. Albumin, three plus. Globulin, three plus. Fehling's reduction, three plus. Wassermann, of both spinal fluid and blood, negative.

The relief of symptoms following lumbar puncture was phenomenal. The prompt alleviation of the headache, stupor, muscle pain and stiffness was dramatically striking and noteworthy. However, four days later patient was seized with a mild convulsion, and immediately relapsed into a condition similar to that experienced prior to the lumbar puncture, although less severe.

Lumbar puncture was again performed, and again brought almost instant relief. The spinal fluid was practically of the same quality and quantity as on the previous occasion, giving the identical reactions throughout. Reduction of the intraspinal pressure by lumbar puncture brought definite and permanent relief, and after a short convalescence of three weeks, patient recovered entirely, except for a mild insomnia and slight muscular stiffness, which persisted for one or two weeks longer.

Diagnosis of this condition was pachymeningitis interna hemorrhagica. The etiological factors in this case no doubt were hypertension and alcoholism. In this connection it may be of interest to mention that Kremiansky as early as 1868, by means of experiments performed on dogs, proved conclusively that alcoholism is one of the etiological factors in the production of this condition.

Spinal puncture in cases of pachymeningitis hemorrhagica interna serves a twofold purpose. It is not only a valuable instrument in affording permanent relief to these sufferers, but is also of great service as an important means of diagnosis. Widal, Froin and Chauffard are among the numerous investigators who have thrown much light on this and similar conditions since lumbar puncture was described in 1890.

From hemorrhagic encephalitis this condition may be differentiated by the diagnostic criteria of the latter—somnolence, ophthalmoplegia and profound asthenia; by its diverse symptom complex, by the constant eye symptoms due to the paralysis, such as ptosis, diplopia, etc.

It may be differentiated from hemorrhagic poliomyelitis—which also gives a bloody spinal fluid—by the fact that there is recurrence of hemorrhage in this condition, and by the absence of paralyses which are predominantly the result of spinal cord lesions. In addition, there is always evidence of infection in acute hemorrhagic poliomyelitis, there is marked polymorphonuclear leucocytosis in which the cell count may reach as high as 40,000 and, often, enlargement of the spleen can be made out.

Again, in early cases of encysted hemorrhages, with headache, pupillary contraction, vertigo and mental torpor, cerebral syphilis and brain tumor are suggested. A Wassermann is not of much value in differentiating pachymeningitis from cerebral syphilis, since syphilis is frequently considered to be an etiological factor in the former condition. Differentiation may be accomplished by the fact that a syphilitic meningitis is usually located at the base of the brain and gives rise to ocular and facial palsies, neuralgia, optic atrophy and deafness. These observations were made by Josephine B. Neal (13), who also distinguishes cerebral tumors from pachymeningitis by the difference in the degree of edema of the disk; it is less marked in cerebral tumors.

In addition, pachymeningitis hemorrhagic interna must be diagnosticated from the following conditions: from tuberculous meningitis, pneumococcal meningitis, cerebrospinal meningitis, suppurative meningitis, hydrocephalus, leptomeningitis, brain abscess, apoplexy, sinus thrombosis, etc., and spinal puncture should be employed toward this end. From traumatic meningitis, however, the history of previous trauma will decide the diagnosis.

In conclusion, therefore, it is doubtless evident that the prognosis of pachymeningitis hemorrhagica interna has been greatly influenced through the employment of spinal puncture both as a curative and diagnostic measure, and that the outlook at present is a far more favorable one than existed prior to its application in this particular condition. Until quite recently the opinion has been practically universal that this form of pachymeningitis, when recognized at all, was encountered only at autopsy, and then, often, only by chance. With these facts in mind it seems but logical to urge that this means of differentiation be employed in all cases presenting symptoms of the nature herein referred to in all cases in which the diagnosis is either doubtful or impossible.

Leucemia

MAUDE GLASGOW, M.D., Dr.P.H.,
New York

Our knowledge of leucemia may be said to date from 1845, when Emmet and Craigie, of Edinburgh, each published a report of this affection. Rudolph Virchow soon after confirmed the observations of these investigators, and suggested the name of leucemia for the disease.

The morbid anatomy of leucemia shows the spleen, marrow and lymph glands to be affected, that is, the whole hematopoietic system is involved, the difference in type depending upon the dominance of the myeloid or the lymphoid process. Roughly speaking, two types are recognized, the myeloid and the lymphoid, other varieties being regarded as atypical forms.

Leucemia is said to appear rather more frequently among males than females, and there is apparently an age of election according to type. Thus acute lymphatic leucemia occurs most frequently between the ages of twenty and twenty-five years, with the greatest incidence in the first five years; chronic myeloid leucemia, on the other hand, manifests itself usually between twenty-five and forty years, and the chronic lymphatic form is seen most often between the ages of forty-five and fifty.

There is no trustworthy evidence proving this disease to be hereditary or communicable, but, as a matter of fact, the real nature of the affection is yet to be discovered. It has been known to follow chronic diseases like malaria, tuberculosis and syphilis; it has supervened on acute affections in the oral cavity, and has even been a sequel to influenza. In some instances, the disease has followed a blow. It has occurred during pregnancy. In other cases it has made its appearance when the individual was apparently in perfect health. The duration of an attack of leucemia varies to some extent with its violence, and the majority of cases noted have been of the chronic variety, the latter form being characterized by exacerbations or relapses which form, quite a feature of this hitherto baffling disease, in the majority of cases one of these exacerbations ultimately proving fatal. The myeloid form is more chronic than the lymphoid, as well as more responsive to treatment.

The onset is in most cases insidious. The growth of the spleen causes an enlargement of the abdomen, often accompanied by shortness of breath, palpitation, anemia and weakness, which cause the patient to seek medical advice. Epistaxis frequently occurs, and there may be gastrointestinal symptoms. The blood picture in all forms presents an excessive number of leucocytes, with a deficient hemoglobin and low erythrocyte count. The myelocytes which characterize the myeloid form of leucemia are said to be the precursors of the polynuclear neutrophile cells, and to result from an overstimulated hematopoiesis which is actively producing these immature cells in the bone marrow.

A rise in basal metabolism corresponding to the severity of the case has been observed, also an increase in protein metabolism, with a greatly increased output of uric acid, a retention of phosphates, and a loss of calcium. Treatment by the x ray still further stimulates this basal metabolism rate.

The agents most commonly used in the treatment of leucemia at the present time, in addition to a generous diet and such aids as bone marrow, iron and arsenic, are the x ray, radium and benzol. Thorium x has also been used.

Each physician has his own favorite remedy and method of treatment, which means, of course, that as yet there is no established agent or method of cure. The prognosis still remains doubtful. Osler says "recovery is practically unknown." Certainly a decade or so ago every case was considered altogether hopeless.

It is quite natural that each worker should extol the particular agent he has himself employed. The opinion has been expressed that benzol, if carefully used, will afford more rapid and certain results than other remedies, yet in large doses benzol has provoked violent renal inflammations, hemorrhage and leucopenia, therefore benzol treatment, like that by the x ray, is a two edged sword, and must be used with caution and intelligence. Unskilful or careless use of these powerful agents results in the destruction of hematogenetic organs themselves, with disastrous results. When the x ray is used, applications to the long bones rather than to the spleen have been advocated. The x ray is said to modify the leucemic process by exciting an inhibitive degeneration while the process itself remains unchanged. The immediate action of the x ray is apparently degenerative leading to a decrease of leucocytes as well as of the red cells. This phase is followed by a reaction, and a more or less resistant type of cell appears, the essential process, however, remaining unchanged, though in character it has undergone an alteration.

It is believed that the action of the x ray produces a leucolytic substance capable of destroying other leucocytes, for the serum of patients undergoing treatment for leucemia by means of the x ray will, if injected into other patients, cause a fall in the leucocyte count, while serum obtained before radiation and similarly injected will have no such effect. When the x ray is applied directly to the spleen we have, when the blood count is made, a toxemic process. These symptoms are less in evidence if only two or three small areas are treated at a time. The statement has been made that if the patient is kept under observation, and treatment renewed when recurrence is noted, he may maintain a reasonable degree of efficiency and be enabled to continue his work indefinitely. It has also been found that the leucocytes do not respond so readily to treatment after the first or second series of applications. During the treatment of leucemia by means of radium the white cells have shown a diminution in number in twenty-four to seventy-four hours. The

decrease in the white cells is often rapid and may continue for weeks after treatment, and at the same time an improvement is noticed in the differential count; but if too much radium is used a retrograde change ensues and the patient grows worse instead of better. The use of radium has been recommended at intervals of one to three months, applications being made to the spleen, but allowing the effects of one application to subside before instituting another treatment. In the use of the agents just described it is evident that the care and skill of the operator counts for much in the progress of the patient.

The case reported herewith is one of myeloid leucemia which occurred in my practice.

Case I.—The patient was an unmarried woman forty-five years old, by occupation a dressmaker. Her father died of pneumonia at sixty-four; her mother died at thirty from an unknown cause; one brother died of dropsy at thirty-nine; four sisters are alive and well; the patient is the youngest girl. There was no family history of nervous or cardiac diseases, rheumatism, cancer or insanity. The patient had had measles and mumps in childhood, and had an attack of influenza in 1921; otherwise she had enjoyed good health. She was thin, her complexion sallow and pale, and she looked frail and tired.

The oral cavity was negative. In the neck the posterior cervical glands were palpable on both sides and venous pulsation could be seen in the neck. The special senses were negative; pulmonary system was negative; the heart was slightly enlarged with a distinct, harsh, presystolic murmur at the apex. The menstrual history was negative except for an uneventful menopause at thirty-five. The skin of the abdomen was dry and the walls tense, and on palpation a hard unyielding mass was found filling the whole left side of the pelvis extending three to four centimetres to the right of the umbilicus and reaching down to the pubes. The inguinal nodes were palpable but not large. The extremities were markedly edematous, and the legs and feet were swollen so that patient had had to procure a larger pair of shoes. Reflexes were normal.

The patient had had influenza a year ago and had not felt well since, some months later noticing that she grew tired quickly when walking. During the past six months she had lost fifteen pounds, and when examined her weight was ninety pounds. During the past few months she had had frequent attacks of epistaxis. Appetite was good, there was no nausea or vomiting, and no abdominal distress. Blood pressure when first taken registered 120 systolic, 55 diastolic, and a few days later the systolic pressure was 105. Uranalysis findings were negative, except for a slight trace of albumin.

The patient entered the New York Infirmary for Women and Children on January 23rd, where she remained five weeks. Blood counts were made by Dr. Elsie Barthels. The first showed: hemoglobin, forty per cent.; red blood cells, 1,832,000; white blood cells, 78,000. Differential count showed myelocytes fifty-five per cent.; polymorphonuclears, thirty-five per cent.; lymphocytes, five per cent.; transitionals, three per cent.; eosinophiles, eight per cent. Fluoroscopic examination showed the stomach pushed by mass into right lower quadrant of abdomen; Cap was perfect and pointing to left. On February 28th a transfusion of 750 c.c. of blood was given by Dr. Unger.

On the 26th x ray treatments were instituted. These treatments were given by Dr. Joseph M. Steiner to whom the patient owed a great deal. Twenty-two treatments were given in all and according to the following formula: 280,000 volts; four milliamperes; distance fifty centimetres; time of treatment, five minutes. The doses were given alternately over the anterior, posterior, and lateral aspects of the spleen, using ten by ten centimetre ports of entry. Dr. Steiner said it was evident that this small dose of radium and the virtue in the radiation apparently lay in the repeated doses at fairly short intervals. Radiation was discontinued as soon as the white count dropped perceptibly below normal.

The spleen decreased in size very slowly but the patient was growing stronger and feeling better. She left the hospital on March 1st, but the radiation was continued until May 2nd. On leaving the hospital her weight was seventy-eight pounds, the edema of her extremities had long since disappeared; no heart murmur could be heard. The spleen was still large but was receding slowly; there was marked improvement in the general condition. Blood count made before leaving hospital was as follows: hemoglobin, fifty per cent.; red blood cells, 2,400,000; white blood cells, 18,000. Differential count: polymorphonuclears, fifty-eight per cent.; myelocytes, twenty-eight per cent.; lymphocytes, ten per cent.; transitionals, four per cent.; nucleated, red cells four. After leaving the hospital the patient was seen at monthly intervals; the spleen seemed perceptibly smaller at each visit until in July it was no longer palpable.

Some poikilocytosis was discernible through the greater part of the summer but the myelocyte count was approaching normality. It was evident that the treatments given during the winter and spring months were still causing a reaction, for the leucocytes count kept dropping until it reached 24,000 which raised the interesting question of just at what stage of the descent of the white blood cells should treatment be discontinued in order to prevent too great loss of the protecting army of the white cells. No myelocytes and no nucleated red cells have been found since September, 1922. The last count, which was made on February 19, 1923, is as follows: hemoglobin, eighty-two per cent.; red blood cells, 6,182,000; white blood cells, 8,200. Differential: polymorphonuclears, eighty-three per cent.; transitionals, five per cent.; lymphocytes, five per cent.; lm., seven per cent.; myelocytes, none seen.

The patient was suffering from a slight cold but otherwise appeared well. She had reached her normal weight of 128 pounds, and has resumed her occupation. She was no longer fatigued by slight exertion, had a good appetite and slept well. There had been no sign of an exacerbation of the disease, which we were taught we must expect, in twelve months of steady improvement. The history of this case encourages one to believe that with the newer methods of treatment for this hitherto fatal disease the prognosis may be entirely changed.

Historical Medicine

A Psychohistorical Study of the Sex Balance in Greek Art*

L. PIERCE CLARK, M.D.,
and HERBERT R. CROSS, Ph.D.,
New York

It is my purpose to present the data of this paper in the natural but reverse order from that which usually obtains. Illustrations will be given first and a general explanation of the phenomena will follow. The natural order to which I refer is the manner one is impressed first with the peculiarity of the general data observed and the common principle that seems to control the phenomena; later some general laws are found which seem to govern the facts, and these are given to prove the assumed correctness of the earlier observations. Many other psychohistorical and art studies might also lend themselves to this manner of treatment and thereby gain much in interest and general vividness of presentation.

Ancient Greek ideals of manhood and womanhood as expressed in the surviving remnants of their sculpture would seem to be based on the theory that the finest and noblest examples both of men and of women are made up of a blend and poise between the essential physical and spiritual characteristics of the male and the female. Since Greek art was founded upon the same ideals of truth and beauty that informed and inspired all Greek life, it follows that their sculpture, so far as it has come down to us, offers an important body of trustworthy, contemporary evidence as to the bodily and mental make-up of their ideal men and women. From a visual review of this sculptural material, it is evident that the Greek ideal was, for their men, a subtle and temperate infusion of qualities characteristically feminine, such as gentleness, sensitiveness, beauty, into a nature preponderantly strong, robust, independent, virile, and for the women, a tempering of their soft, sensitive, clinging nature and their delicate, seductive charm by the inclusion of a touch of masculine or boyish qualities, so as to make them less unqualifiedly feminine, while still finely womanly.

FIG. 1.—Apollo from Tenea, Munich. Archaic period (early sixth century). An example of the modification in the early period of Greek art of the masculine ideal by the addition of a certain amount of grace.

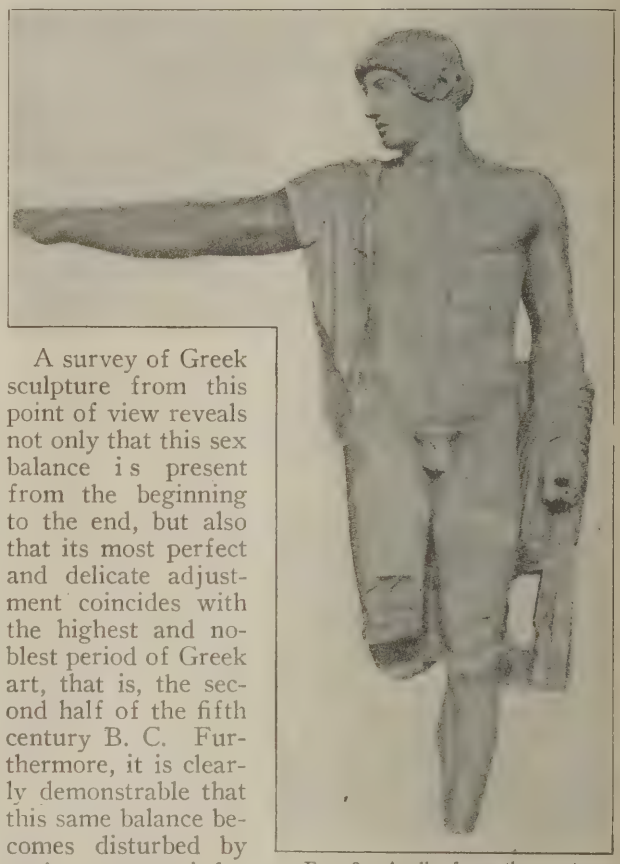

FIG. 2.—Apollo from the western pediment of the temple of Zeus at Olympia. Second quarter of the fifth century. An example of the somewhat dry and imperfect technic of the transitional period, yet showing the increasing tendency to express grace and beauty in the athletic male body.

A survey of Greek sculpture from this point of view reveals not only that this sex balance is present from the beginning to the end, but also that its most perfect and delicate adjustment coincides with the highest and noblest period of Greek art, that is, the second half of the fifth century B. C. Furthermore, it is clearly demonstrable that this same balance becomes disturbed by an intemperate infusion of qualities of the opposite sex as the evolution proceeds from the fourth century into the Hellenistic period, or else it becomes entirely eliminated and the types revert to primitive masculinity or unmitigated femininity.

The history of the development of Greek sculpture from its dim beginnings in the seventh century, through the great period of the fifth and fourth centuries, through its long autumn in the Hellenistic period to its final disintegration after the Roman conquest in the second century B. C., all this is now sufficiently well known through extant monumental evidence, so it is possible to follow the evolution of Hellenic sex ideals throughout five centuries by still visible and available material. In dealing with the actual sculptural remains, however, great care must be exercised to distinguish between original Greek works and Roman or other copies, for there is a noticeable tendency on the part of the copyist to modify the original from which he was working in accordance with his own taste or that of his time which will cause him to disturb the fine balance and

*Presented before Historical Section, New York Academy of Medicine, November 30, 1923.

temperance of the original by accenting unduly certain qualities and slighting or omitting others. Any effective demonstration of this problem must be by means of abundant illustration, yet without that invaluable aid a summary of the evolution may be attempted in brief compass. The arguments centre mostly around the masculine ideals, for not only was the male the dominant sex among the Greeks, but the sculptors were, without exception, men. That the whole question has a strongly homosexual tinge goes without saying.

Throughout all the archaic period Greek sculptors were too heavily handicapped by imperfect technical skill to express adequately the finer points of characterization, yet even in the midst of their efforts to master the facts of the proportions of the human body, the folds of drapery or the texture of hair and flesh, we find them endeavoring as best they might to portray certain subtle refinements in their types, never before attempted in the history of art. After the archaic, or more exactly, the transitional period, the artist's skill becomes entirely adequate even for the most difficult or delicate problems and we can thenceforward assume its sufficiency.

Fig. 3.—Head of the charioteer of Delphi (from a cast). First half of the fifth century B. C.

Even in the primitive art of the seventh and sixth centuries, one finds the modifications of the absolute "hundred per cent. male" ideal of courage, strength, simplicity, directness, by an infusion of grace, refinement, beauty. This is very clear in a series of ideal nude male figures from this period known under the generic name of *Apollos*. The series reveals from the start, and shows with increasing skill and clarity, not only the determination to make the male body correctly proportioned, strong, well built, well developed, but also to make it fine, to add beauty to the modeling and sensitiveness to the features. An attempt to portray the beauty of curly hair is invariably found. The *Apollo from Thera,* the *Apollo from Tenea* (Fig. 1) and the *Strangford Apollo* are typical examples. For all their crudity, they show indubitable signs of refinement and grace. This will be clear at a glance if one compares them with figures from Chaldean or Assyrian art, such as the brutal virility of the statues from Tello in the Louvre or the reliefs from Nineveh in the British Museum.

A study of the long line of *Maidens* or *Aunties* from the Athenian acropolis shows the tendency of the early Attic sculptors, with their strong Ionic affiliations through the school of Chios, to make their female ideal over delicate and dainty, even fussily elaborate, and too desirous to please. The figure from this series, a late one, known as *la Boudeuse,* shows a wholesome reaction against this excessive femininity, probably due to Peloponnesian influence, and interestingly foreshadows the noble womanliness of the female types which were produced at Athens by Pheidias in the next century.

In the transitional period, between the close of the Persian Wars and the middle of the fifth century, not only does technic become increasingly able to portray delicate refinements, but an ideal blending of masculine and feminine qualities in one person seems to be more clearly in the mind of the sculptor. In the robust and somewhat drily modeled *Apollo* (Fig. 2) quelling the riot of the Centaurs, from the west pediment of the Temple of Zeus at Olympia, there is a noticeable tendency towards refinement and grace. The same is true of the *Choiseul-Gouffer Apollo* in the British Museum, while the famous bronze *Charioteer of Delphi* (Fig. 3), for all its nobility, shows a refinement of build and a delicacy, especially of the hands and feet, almost inconsistent with the idea of a chariot racer. The very refined treatment of the hair, the voluptuous mouth and the full chin reveal the Ionic character of the work and tend to confirm Calamis as the author.

The second half of the fifth century witnessed the loftiest and noblest point reached by Greek sculpture. This period is dominated by three great artistic personalities, Myron, Polyclitus and Pheidias. It is noteworthy that tradition says all these were trained in the severe Doric school of Ageladas. The first two were primarily concerned in the representation of athletic types, Myron, of those in motion, Polyclitus, of those in repose. In Myron's well known *Discobolus,* though the figure is lean, clear cut and unemotional, there is very great grace and beauty in the difficult but successful pose. In the massive square cut and powerful *Doryphorus* (Fig. 4) of Polyclitus and in the slightly more slender and youthful *Diadumenus* by the same master, it is somewhat surprising to find so much emphasis placed upon the beautiful reversed curved line that forms the basis of both pose and composition in both figures. It is almost Hogarth's "line of beauty" and imparts a feminine touch to an athletic type otherwise thoroughly vigorous and masculine.

Their Athenian contemporary, Pheidias, has been exalted in modern critical opinion, to the absolute first place among all artists of classical antiquity. He was not primarily the sculptor of athletes but of divinities and to him is due the signal distinction of fixing for all subsequent time the essential types both of Zeus and of Athene. Unrivalled in his power to express the serene strength and Olympian majesty of the gods, he may be said to have summed up in visible form the highest spiritual and religious ideas of the Greeks. In his grandest statues of divinities, the colossal gold and ivory images of Zeus at Olympia and of Athena Parthenos at Athens, he seems to have given to each a strong infusion of qualities of the opposite sex. The homosexual incident recorded in Pheidias's career may not be with-

Fig. 4.—The Doryphorus of Polyclitus. Second half of the fifth century B. C. Direct robust masculinity but modified by a graceful round curve running through the body.

Fig. 5.—Head of the Athena Lemnia of Pheidias. Marble copy in the Musso Civico, Bologna. Second half of the fifth century. B. C. This head was long called "Head of an athlete."

Fig. 7.—Aphrodite of Melos, upper portion of figure. End of fifth century B. C.

Fig. 6.—The Three Fates, from the eastern pediment of the Parthenon, showing in their largeness and robustness of proportion and build a distinct tempering of the essential feminine character. Second half of the fifth century, B. C., Pheidias.

out significance in this regard, yet his *Zeus* was essentially noble and powerful, and his Athena types never approached the virago.

The extant copy of his famous *Athena Lemnia* (Fig. 5), so ingeniously recovered by Furtwängler, through a torso in Dresden and a head in Bologna, reveals the master's exquisite discretion in this matter of sex balance. He has shown us a maiden goddess, cool, poised, self sufficient and yet eminently womanly and beautiful. Especially to the head, with its simplified silhouette and modeling, he has imparted a boyish touch, so that it is quite intelligible how the exquisite Bologna copy of it was called *Head of an Athlete* before its true identity was discovered.

Similarly, that extraordinarily grand and beautiful trio of female figures from the east pediment of the Parthenon, called *The Three Fates* (Fig. 6), show a distinctly tempered femininity. Their robust and ample build, their air of repose and dignity, convey a sense of masculine quality and are responsible in large measure for the intensely Olympian character they bear.

Passing to that noble derivation from the art of Pheidias, the *Aphrodite of Melos* (Fig. 7), so lovely in her perfect womanhood that she seems to the modern mind to embody all that is finest as well as loveliest in her sex—this work even shows a sufficient tinge of largeness, poise and strength to modify her considerably from the utterly feminine. A comparison of the *Aphrodite of Melos* with the *Aphrodite of Cnidus* by Praxiteles (Fig. 8), and the *Venus de Medici* (Fig. 9), both of the fourth century, will show that in these latter this hint of the masculine is omitted, and they become distinctly less divine. Indeed the Medicean statue, for all its clever technic, is little more than a representation of an extremely pretty woman in a pose of mock modesty.

The Pheidian male creations, such as the greatly praised *Theseus* from the east pediment of the Parthenon, or the *Apollo from the Tiber,* embody unmistakable qualities of grace, refinement and beauty, but not in such measure as to overbalance their masculinity. This is interestingly compared to the close approach towards overmuch sensitiveness seen in the creations of the greatest Attic master of the fourth century, Praxiteles. In his works we feel that the scale which Pheidias kept on the side of Doric restraint, inclines now towards Ionic softness and voluptuousness. His *Hermes of Olympia* (Fig. 11) in spite of his masculine frame and splendid muscles has both in pose and modeling and

Fig. 8.—Aphrodite of Cnidus. Fourth century B. C. Dreaming and graceful with very slight modification of the purely feminine, midway between Aphrodite of Melos and Venus de Medici.

Fig. 9.—The Venus de Medici. Uffizi gallery, Florence. In the elimination of the masculine infusion seen in the older fifth century ideal of Aphrodite, this figure goes beyond the Aphrodite of Cnidus and loses nearly all hint of divinity. She is little more than an extremely pretty woman in a pose of mock modesty.

facial expression so much beauty and dreamy languor as to come close to the borderline of the too much. This is also true of his *Faun,* his *Apollo Sauroctonus* and other male figures, yet it should be said in defense of Praxiteles that the exaggerated softness and effeminacy, too frequently encountered in replicas of his works, are undoubtedly due to the overaccentuation of the copyist and did not exist in such disproportion in the originals. It is much fairer to the master to argue from the *Hermes,* which, by a miracle of good fortune, has survived into our day almost as it came from Praxiteles' hand. In the head of this work it is instructive to see how, in spite of the soft, silky texture of the close cropped curls, the essentially masculine shape of the head has been made clear, and, for all the dreaminess of the eyes and the delicately smiling lips, it is the broad brow, with the strong accentuation of the masculine frontal sinus that dominates the features.

Still it cannot be denied that Praxiteles' works all tend towards the excessive grace and effeminacy which becomes more clearly marked as Greek sculpture goes on through the fourth century into the Hellenistic period.

The contemporary works of Scopas, while showing the typical fourth century preoccupation with emotion, deal for the most part with a surging, fiery passion, expressed in energetic, masculine terms, as in the fragmentary heads from Tegea, or the many copies of the passionate *Meleager.* The head of the *Lansdowne Heracles* has an almost feminine wistfulness and reminds us that Scopas is recorded to have done statues of *Longing* and *Desire.*

The third member of the great fourth century trio, Lysippus, was much less emotional in his art and continued the sterner Doric tradition, though he heightened the masculine figure, made it more slender and elegant than the figures of Polyclitus and imparted a more lively expression to his works.

In the Hellenistic period (from the death of Alexander to the Roman invasion), there seems to be a clear parting of the ways. One branch of Greek sculpture continues the overdoing of softness and voluptuousness in the male type until the result is markedly effeminate. From this period date those *Apollos* expressed in absolutely feminine curves and elaborate coiffures (Fig. 12); also a head in the Capitolium Museum, now recognized as *Bacchus,* but long called by the name of his wife, *Ariadne,* while the sex of the puzzling *Fanciulla d'Anzio* (Fig. 13), in spite of the good preservation of the statue, has never been conclusively determined. The sculptors of this late period go even one step further and create a new type, the *Hermaphrodite* (Fig. 14), of which a number of fine examples are known.

Running parallel through this same period a second branch of Greek sculpture reverts more and more to the simple unmixed types of men and women, until finally we have such ignoble and repellent, unmodified masculine representations as the great, hulking *Hercules Farnese* (Fig. 15), of the Naples Museum or the utterly brutal, bruiser type exemplified, with great skill, in the naked bronze *Boxer* of the Terme Museum in Rome. These "hundred per cent. masculine," cavemen ideals have their feminine counterparts in the long series of so-called Venuses of the Hellenistic period. The *Venus of the Capitol,* the *Crouching Venus* of the Vatican, (Fig. 16) and other museums, the ignoble *Venus Callipyge* of the Naples Museum, adequately represent the wretched descent from the truly Olympian Aphrodite of the older times to the seductive vamp of the close of Greek sculpture as a living art.

If space permitted, an interesting and close analogy between these ideals in Greek sculpture and similar ones in Greek architecture might be drawn. The two principal Greek orders, the Doric and the Ionic (the Corinthian being merely a variant of the latter) embody respectively masculine and feminine qualities and came, the one from the hardier, severer Dorian peoples of Greece, the other from the more refined and luxury loving Ionian peoples, but it is significant that the finest and noblest example of Doric architecture, the Parthenon, has undeniable Ionic elements in it and the Temple of Nike Apteros, one of the most perfect embodiments of Ionic, is distinctly sturdier and more simple than the typical Ionic temples of Ionia itself. Again, the lesson seems to be, as in the sculpture, not too much of either masculinity or femininity, of either sheer strength or of soft beauty, but instead a realization of the ideal of temperance expressed in the old Greek motto, "μηδὲν ἄγαν," "nothing in excess."

* * *

In the consideration of the principles demonstrated in the foregoing, an explanation of the same will now be given. We will consider the essential dynamic nature of this sex imbalance.

To those who wish to connote no special love trend in this double inheritance of sex characteristics, the term bisexual constitution is used, but to those who maintain a psychophysiological view of these characters, that they continue essentially to strive for a specific love objective, the term homosexuality is used. The bisexual term is a static one, while homosexuality implies a more vital and physiological one. We prefer the latter, though both may be used if one notes that the first is static and constitutional while the latter is psychobiological or physiological. We will review briefly the general social and legal status of homosexuality in Greek times. There are so many documents on this subject that it is difficult to choose; homosexuality was either approved of or tolerated, from early and prehistoric times. The boy Eros, god of love, equivalent to the Latin Cupid, was more than a symbol, for in some places he typified the object of sexual love. In the island of Thera, one of the Cyclades, there are ancient inscriptions which are not examples of mere obscenity, but show the existence of an ancient cult of the boy Eros.

Homosexuality was not an appanage of the decadent period of Greece nor smuggled in from Asia but evidently belongs to an old native cult. Reasons for its existence and its justification were given by scientists, politicians and military men. The former asserted that man was a bisexual creature. He being half man and half woman could be an object of male love. Another explanation was that not all men but some of them were half female. All human beings were double—some were double men, some double women and others half and half; the latter were presumably the objects of male love.

(To be continued)

Editorial Articles

A NEW ANTITUBERCULOUS VACCINE

Studying the means of specific treatment of tuberculosis, Baufle and Daguet (*Revue méd. de la Franche-Comté,* July 15, 1922) have attempted to prepare a vaccine possessing a diagnostic, prognostic, prophylactic and therapeutic action at the same time. By analogy with what at present is being accomplished in a large number of infectious diseases—Delbet's vaccine, autovaccine, antigonococcal vaccine, and others, these observers have tried to obtain from products excreted by the tuberculous patient in the sputum a preparation of the type of specific vaccines. They utilized a vaccine obtained by dissolving sputum in various artificial liquids; the resulting solution being filtered by various procedures was given subcutaneously in doses varying from one third c. c. to one c. c. in a series of from five to ten injections given every second to fourth day.

A year's work has given the following results: In patients presenting a slow evolution of their tuberculosis or who resist the infection, the injections do not give rise to any local reaction—no redness, pain, heat or swelling. In other instances a very sharp reaction ensues, generally three to four hours after the injection. The redness extends in the form of a plaque varying in size from a twenty-five cent piece to the palm of the hand, or even larger, being occasionally rather painful with or without swelling and without lymphatic enlargement, all being analogous symptoms—although much more accentuated—to those produced by intradermic reaction with tuberculin. Then, in twenty-four to forty-eight hours everything subsides, and in fifteen to thirty days or more, a collection of pus about the size of a walnut develops at the site of the injection, opens spontaneously rather quickly giving issue to thick pus and resulting in an ulceration which slowly cicatrizes. In the majority of cases the sites of injection are in chronological order, the seat of an abscess having an identical evolution.

Finally, in some cases there may at first be no local reaction but later on an indurated nodule develops at the site of inoculation which goes on to abscess formation. Microscopic examination of the pus of the abscess—whether acute or chronic in evolution—revealed the presence of avirulent Koch's bacillus, because inoculation in the guineapig did not give rise to any tuberculous lesion as was shown by autopsy of the animals after a lapse of three months.

The general state of the patient reacts differently in the various cases. Patients running a high temperature do not have any further rise; on the contrary the temperature subsides and becomes completely normal. On the other hand, a subject that has usually been apyretic may present a temperature of 103° F. but this will drop to the previous apyrexia in a few days. Lastly, there are other subjects with or without pyrexia whose temperature chart is not influenced by one tenth of a degree after injections of the vaccine.

The absence of a local or general reaction most generally indicates a tuberculous process having a rapidly fatal evolution with laryngeal, meningeal, intestinal or septicemic complications. On the other hand, in some cases, the patients less frequently offer a wonderful organic resistance, the tuberculous process having ceased in its evolution, and no local or general reaction ensues. The development of a local and general reaction, and especially the development of an acute or chronic abscess at the site of the inoculation, would seem to indicate an appreciable defensive state, and in reality, in some after a few weeks there will be complete apyrexia, a very evident improvement of the general health, while at the same time the physical signs subside and the sputum and bacilli become far less abundant. Several patients followed for some time continued to show improvement while others placed in deplorable hygienic conditions relapsed and their condition became notably aggravated.

To sum up, it can be said that antituberculous vaccination by means of the sputum of patients appears to be a possibility and is inoffensive as shown by the results of guineapig inoculation. It frequently allows one to make a prognosis of the value of the resistance of the patient, likewise the gravity of the affection. Combined with sanatorium treatment and artificial pneumothorax vaccination would seem to offer much in the treatment of pulmonary tuberculosis.

OLD TIME PRACTICE OF MEDICINE AND THERAPEUTICS

Time was, and not so long ago, when the practice of medicine was not scientific, nor, indeed, was therapy. Glimpses can be had of what the rank and file of eighteenth century doctors were like, when Dr. Slop in *Tristram Shandy* is recalled. If Slop be considered a caricature, as doubtless he was to some extent, the apothecaries and surgeons in the novels

of Tobias Smollett, who himself belonged to the profession, may be turned to. Again, the father of Pendennis in Thackeray's novel is a good representation of what the country practitioner in England was at a later date.

The prescriptions of the medical men in those days, and even forty or fifty years ago, were comparatively simple, the synthetic remedies being unknown. Quinine for a cold in the head, a blue pill and a black draught for a sluggish liver, a hop pillow to induce sleep and cupping for full blooded individuals were among the popular and fairly effective remedies used then. They must have been curative or palliative, or they would not have been employed so extensively; of course, psychology enters somewhat largely into this question. When a patient is convinced that a particular medicine will do him good, or is having a beneficial effect, the whole setting of the mind for healthy, suggestive action comes into play, and an excellent illustration is given of the unconscious powers for good. The old time doctors not only were lavish prescribers of medicine, but they believed in the remedies they gave implicitly and therefore their patients did likewise.

John Wesley, the great Methodist, who, together with that wonderful orator, George Whitefield, evangelized a large proportion of the population of England, doctored the bodies as well as the souls of his converts. He wrote a book named *Primitive Physic,* a small octavo volume of just over one hundred pages, which appeared in 1747. In the preface to this book, written in the strong, lucid and simple language of which Wesley was a master, he denounced the medical practitioners of his day in unmeasured terms of contempt. He drew up and published "a plain and easy way of curing diseases," which gave several hundreds of remedies classified for some two hundred and fifty different ailments. He added: "I have only consulted herein, experience, common sense, and the common interest of mankind. And supposing they can be cured in this easy way, who would desire to use any other? Who would not wish to have a physician always in his house, and one that attends without fee or reward? To be able, unless in some few complicated cases, to prescribe to his family as well as himself."

The receipts given in *Primitive Physic* consist mainly of ancient traditional remedies handed down through generations of wise women. Not a few may be found in the old Herbals. Many of them are extremely quaint. This one for asthma, for instance: "Live a fortnight on boiled carrots only. It seldom fails." Or this for ague: "Apply to the stomach a large onion slit. Or eat a small lemon, rind and all." Or this for whooping cough: "Rub the feet thoroughly with hog's lard, before the fire, at going to bed, and keep the child warm therein. Or rub the back at lying down with old rum. It seldom fails."

No fewer than fifteen remedies are given for "a consumption," some of which are very strange and curious. For example: "Take no food but new buttermilk, churned in a bottle, and white bread," or, "every morning cut up a little turf of fresh earth, and, lying down, breathe into the hole for a quarter of an hour," or, "drink twice a day two spoonfuls of juice of water cresses." At any rate, none of these remedies were harmful and, combined with faith, might and no doubt did good. It may be pointed out that there is almost a fashion in drugs, and most of the drugs which were employed by the old time doctors have been discarded in spite of the fact that many of them were considered to be and seemed to have proved themselves of signal service. Perhaps the famous and witty French physician was right when, in giving advice to a newly fledged young doctor, he said, "Hurry up, my boy, and prescribe this remedy whilst it is doing good."

There appears to be some signs that certain simple old fashioned remedies are coming into vogue again. The medical man, too, of fifty years ago, although he could lay no claim to being scientific, was usually a good clinician. He had been trained in the hard school of experience. Today, perhaps, he is more probably too much of the scientific man and not enough of the clinician. However, other times, other manners.

In connection with the theme of old time practice of medicine, it is pertinent to refer to a paper, one of a series, which appeared in the London *Lancet* November 1st last by Sir James Mackenzie, who is now doing research work at the St. Andrew's Institute of Clinical Research, founded by him. He says that, in his opinion, little more is known about disease than forty years ago. He goes on to say that if the present state of knowledge and practice regarding these diseases, the common diseases of the country, be compared with the state when he entered practice forty-five years ago, there is some difficulty in recognizing where progress has been made. The socalled minor ailments, some of which are the beginnings of serious ill health, the numerous digestive troubles which do so much to impair health, are just as common and as little understood now as then, and we are just as helpless in the face of grave acute disease. Progress in medicine may have been somewhat slow, but it seems that Sir James Mackenzie is too pessimistic. For example, in the domain of disease, which he has largely made his own, that of the heart, mainly through his own work manifest progress has been made. He contends that the beginnings of disease are not recognized so that

these may be nipped in bud, and serious conditions prevented from developing. He also holds that too much attention is paid to laboratory research and not enough to clinical work. One should be the complement of the other. The practitioner of forty or fifty years ago had perforce to be a good clinician, as observation, supported by practical experience, was all he had to rely on. The consequence was that then good clinicians were numerous. Nowadays, perhaps, the pendulum has swung too far in the opposite direction and reliance is largely placed on the results of laboratory investigation. Research and clinical work should go hand in hand, but thorough clinical training should never be neglected and some of the old time medical teaching and methods are far too valuable to be omitted or treated inadequately.

THE PATHOLOGY OF MISERY

Investigations carried on in 1919 by Professor Demoor of the Brussels School of Medicine showed that the average weight of all children of all ages had been retarded. For height the children were from one seventh to one half year behind the normal attainment for height and about a year for weight. The retardation of development was especially marked among the poorer population. This was part and parcel of what has been termed the pathology of misery, for which the primary cause was war. A like condition existed and exists in Austria and Germany.

A different picture is presented by the children of England, where, since 1913, there has been, according to Dr. Hamer, the county and school health officer for London, a steady improvement in the general physical condition of school children. In Belgium, along with slowing up of growth there went an increase in diseases of all kinds. In London, according to Dr. Hamer's 1921 report, the percentage of rickets among entrants (school life in England may begin at three or four years) has fallen from 22.6 to 14.1 per cent., ten per cent. more children have sound teeth than was the case eight years ago, and the general evidence of disease is less.

England also was at war, but the war brought with it more work and more pay for the parents and more and better food for the children than they had ever known. It was an artificial condition and there may be a relapse with present unemployment and high cost of living but in the meanwhile it has afforded a striking object lesson, especially when contrasted with the companion picture from the continent, of what economic conditions must be kept in mind in all health work and in any statistical conclusion as to what has been done or is being accomplished along lines of public health.

Feeding and housing are basic conditions for health, and feeding and housing cost money. Any agency that reduces the cost of food or lowers the rent of houses (or furnishes a more sanitary home for the same cost) is as much a power for health as all the professional hygienists and, in fact, the work of the latter is of little avail if it leads not to the former. A justified strike for higher wages may be at the same time a strike for higher health for those who are dependent on the striker. We have not such dire social conditions in this country as exist in Europe, though in many of our cities the pathology of misery exists to a greater degree than we wish to think. Moreover, there are huddled here a horde of children who, in the homes of their forbears would at least have enjoyed the conditions of country life and a better choice of food. Better wages, better homes, better schools, better playgrounds are more needed than larger and more palatial hospitals for overcoming what Newsholme has well styled "the horrors of peace."

THE PSYCHOPATH IN DRAMA

Fiction and the stage contain numerous excellent portrayals of psychopathic types. A notable example of this is the character of Rufe Pryor, acted with remarkable realism by John Hamilton in Hatcher Hughes' vivid folkplay of the North Carolina mountains, *Hell-Bent fer Heaven*.

Rufe is a case of constitutional psychopathic inferiority of the inadequate personality type, developing into the criminal type with religious compensation under the influence of aroused and inhibited sex instinct. Coming from a family with a reputation for lack of courage—his grandfather was reputed to have knocked out his front teeth to escape enlisting in the Confederate army—and having lost his mother when he was an infant, Rufe is the pathetic victim of a bad heredity and a neglected childhood. His neighbors and the husky, practical-minded men of the mountain family with whom he lives as a sort of boundboy, consider him "quair," "womanish," "tetchy," lazy and hypocritical, the last especially because he has lately fallen in love with the pretty Jude and simultaneously "got religion." The women of the family are inclined to pity him, take his part, and believe in his socalled spells and visions of Heaven. His desire to win Jude for himself expresses itself in an obsession to do away with her betrothed, the handsome, vigorous son of the family, whose wholesome personality is presented in striking contrast to Rufe's frail, twisted body with its burning eyes and erratic but

perversely brilliant mind. The love object is quickly made identical by the conscious mind with religious adoration, the orientation coming, perhaps, from the fact that the girl was first seen in church. The whole series of subsequent criminal machinations into which Rufe is led become, to him, the carrying out of divine will to rid the earth of the wicked revilers of his faith and to give him his "spiritual bride." The playwright shows us the tremendous egoism of selfdefensive origin usually present in such a case; the conversion of suggestive incidents, such as a timely clap of thunder, into "messages from on high," and their subsequent development into plans and acts to serve personal ends; the wild fluency, with frequent poetic beauty, in prayers and religious ecstasies, changing almost instantaneously to subtle lies and preternatural cunning in avoiding discovery; the utter callousness to the harm or even death of those conceived as obstructions; and the final selfexposure through the very keynotes of the maladjusted personality (which always tends to self-destruction), namely, constitutional cowardice and religious overcompensation, inducive of superstitious terrors. Poor Rufe escapes from the situation in the only way open to the congenital craven—by running away.

The dramatic conception and presentation of so vivid and truthful a personality study is a significant indication of and tribute to the present day spirit of social mindedness, and the earnest desire on the part of many thinking people to know and understand, from a scientific and therefore practical point of view, more about human nature and the causes operating back of its failures, faults, and even crimes, as well as its successes, hopes and aspirations. Poor Rufe stands forth an eloquent witness to the urgent necessity for a widespread mental hygiene movement. Had he been given, throughout the early years of his life, proper attention, both physical and mental, it is possible that, in spite of the hereditary taint, and in view of his sensitive nature, unusual intellectual potentialities, and artistic sensibilities, combined with the social interests manifested in his mania for saving souls, the tendencies that became "hell bent" might have been transformed into traits of character of service and value to the community.

NEW JOURNAL DEVOTED TO CANCER

Cancer, a Practical Quarterly Journal Devoted to the Best Interests of Cancer, is the title of a new publication of F. A. Davis Company, of Philadelphia. Dr. L. Duncan Bulkley is editor, with Dr. Clarence D. Daniels as associate editor, and Dr. A. Hirst Appel, Dr. Seelye W. Little, Dr. Russell W. Kelsey, Dr. Edward Preble, and Dr. Thomas L. Stedman as collaborators. Dr. Bulkley states in the foreword that "the aim and purpose of this publication are to concentrate in convenient form all that will conduce to a bitter knowledge of cancer as a disease, and its cause and proper treatment, in its different forms and manifestations in various regions of the body, and thus to aid in lowering its steadily rising morbidity and mortality." The journal comprises four sections—original articles, editorials, clinical reports, and reviews of literature.

The initial October number contains contributions as follows: Audi Alteram Partem, by Dr. Stedman; Nature and Cancer, by Dr. Otto Lerch; Considerations of the Cancer Question, by Dr. Daniels; Why I Favor the Systemic Treatment, by Dr. Appel; The Cancer Situation of Today, by Frederick L. Hoffman, LL.D., consulting statistician of the Prudential Insurance Company, and Cancer Death Rate in New York City During 1922, by Dr. Bulkley, who has also a clinical report on a case of cancer of the cervix treated medically. The book reviews are followed by a review of recent literature on the subject of cancer, including statistical data, etiology, immunity, and treatment.

INTERNATIONAL CLINIC OF PLASTIC SURGERY

During and immediately after the war, surgeons gained so much knowledge in obliterating or rendering less unsightly the many disfigurements and deformities from shot and shell wounds that a clinic has been organized in London to preserve, improve and impart this knowledge. Another object which this clinic has is exposure of the quack and of the socalled beauty specialist.

The International Clinic of Plastic Surgery is worldwide in scope, a no profit institution, open to all classes, and with a scale of fees accommodated to the means of the patients. Dentists, artists, and sculptors cooperate with the surgeons in the work. The clinic will issue a quarterly journal dealing with plastic surgery. All financial surplus is to be devoted to tuition, improvements, pensions for the staff, etc. The institution is temporarily housed in a part of St. Andrew's Hospital.

The only students to be admitted will be surgeons of unquestioned standing, for the courses given are in postgraduate work. The director of the clinic is Dr. H. D. Gillies, who was head of the surgical unit of the British Army in charge of reparative cases during the war. The other English member of the teaching and operating staff is Dr. T. Pomfret Kilner. Dr. J. Eastman Sheehan, of New York, and Dr. Ferris N. Smith, of Grand Rapids, Mich., are the American members, and Professor Lemaitre the French.

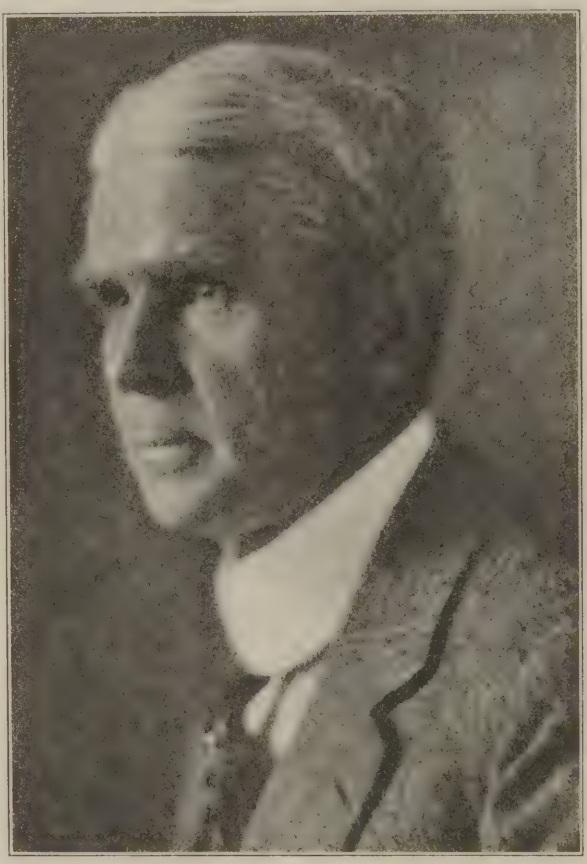
In order to exclude any commercial possibilities from among the staff, all American students must be certified by Dr. Sheehan and Dr. Smith. Qualifications for prospective American students are the same as for membership in the American College of Surgeons, and for English students those of the Royal College of Surgeons. Certificates will be granted upon the satisfactory completion of the courses given at the clinic.

Obituary.

LUTHER EMMET HOLT, M.D.,

New York.

Dr. Holt was born at Webster, N. Y., on March 4, 1855. He received the degree of A. B. from the University of Rochester in 1875 and graduated from the New York College of Physicians and Surgeons in 1880. After an internship in Bellevue Hospital he immediately took up thestudy of diseases of children in an intensive form. Early in his medical career he held the position of attending pediatrist at the New York Infant Asylum, New York Nursery and Childs' Hospital, and the Foundling Hospital. He was professor of diseases of children at the New York Polyclinic Medical School and Hospital from 1890 to 1901 and clinical professor of diseases of children at the College of Physicians and Surgeons from 1901 to 1920. He was a member of the board of directors of the Rockefeller Institute since 1902. The latter institution conferred on him the degrees of Sc. D. and LL. D. The Red Cross appointed him a member of the committee to attend the medical Conference at Cannes in 1919.



L. Emmett Holt.

He was a charter member of the American Pediatric Society and held the office of president in 1898 and 1923. The high place that this society holds in the medical world today is due in no small measure to his advice and counsel. Holt's textbook on *Diseases of Children* has passed through eight editions and is universally accepted as a standard on this subject. His small book on *The Care and Feeding of Infants* is in its twelfth edition and has been translated into four languages, Polish, Spanish, French, and Chinese. His contributions to medical literature on pediatric subjects were voluminous. Dr. Holt was appointed physician in charge of the Babies Hospital in 1889. The hospital at this time occupied a small one story house and had twenty beds. To this institution he devoted his time and talents and largely through his efforts the present building was financed and erected and he has always directed its policies and shaped its destiny. He gave to it the best that was in him and the Babies Hospital will always stand as a monument to his memory.

Through his teachings and publications Dr. Holt wielded a greater influence on child life and has come in closer contact with more children in the home than any other man of his day and generation.

It was a rare privilege to be a student of Dr. Holt. Always a clear thinker, with an analytical mind and an unusual ability for concise expression, he not only taught his students pediatrics, he taught them how to think. It is difficult to state the most striking individual characteristics of such a man as he.

SIR NAPIER BURNETT, M.D.,

London, England

Sir Napier Burnett, chief executive officer of the Order of St. John of Jerusalem in England and of the British Red Cross Society and director of Hospital Services in England and Wales, died at his home in Hampstead, London, on Christmas morning. A few months ago he was obliged to return to England from the continent to undergo an operation which was performed by Professor Wade in Edinburgh. Complications supervened and he never rallied. Twelve days before his death he was removed, at his own request, to his London home.

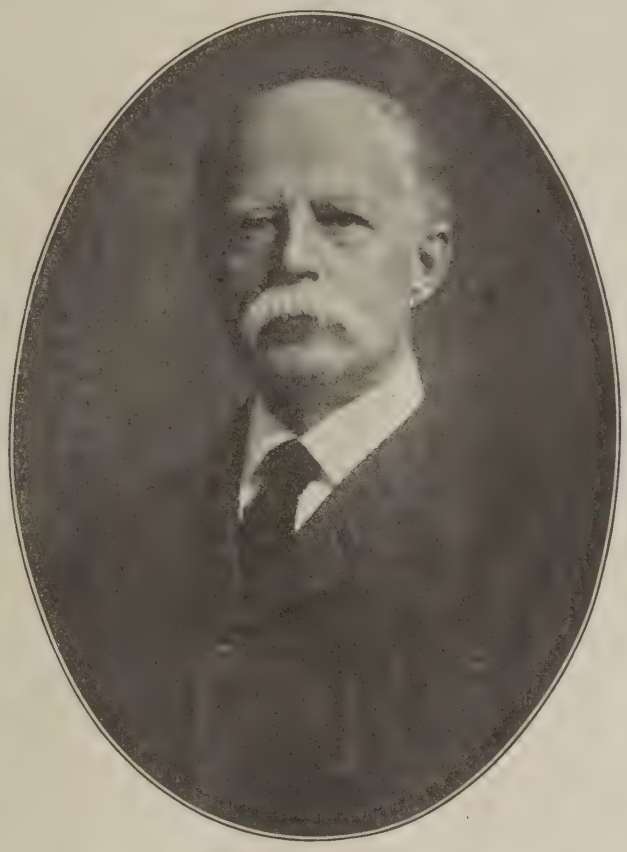
Sir Napier was born in 1872 at Frazerburgh near Aberdeen and received his medical education at Glasgow University where he took the M. D. degree in 1908. He came to Newcastle and began practice there as a consulting obstetrical surgeon. He rendered invaluable service to Newcastle Maternity Hospital and made a close study of hospital organization, and the knowledge gained was in after years of value to the nation.

When the war broke out, with Professor Rutherford Morison he was largely responsible for the organization of the Northumberland War Hospital. When the war was over he returned to Newcastle but still had in his mind the possibility of coordinating the work of the voluntary hospitals and continued his efforts with this aim in view. In 1920 he was appointed Director of Hospital Services under the new scheme whereby the Red Cross was to be stabilized and continue its labors in time of peace. He did much for the voluntary hospitals, mainly by improving their organization. Sir Napier Burnett was really a great organizer and his work during and after the war in endeavoring to stabilize the voluntary hospitals was a national service and won for him national fame. At this juncture he could be ill spared.

EDWARD LAWRENCE KEYES, M.D.,

New York

Edward Lawrence Keyes, A. M., M. D., LL. D., K. S. G., of Tuxedo Park, one of the foremost genitourinary surgeons of this country, died at his New York City residence on January 24th after a brief illness from pneumonia. He was born in 1843 at Charleston, S. C., and was the son of General Erasmus Keyes, U. S. A., descendant of an old New England family. After graduation from Yale in 1863, he served as captain in the army, on his father's staff. The war over, he studied medicine at New York University, and, after graduation, dermatology at the University of Paris. Upon his return to the United States, he was appointed lecturer on that subject to Bellevue Hospital Medical College, then the leading medical college of the country, where he delivered in 1870 the first course of lectures on dermatology given in the United States. For a few years he served as visiting surgeon to City Hospital, then, in 1875, was transferred to Bellevue, where as professor of dermatology, syphilology and genitourinary surgery he established the first ward in this country for genitourinary cases. Dr. Keyes was, during the subsequent fifteen years of incumbency, the most influential teacher of syphilis and genitourinary diseases in the United States.



EDWARD L. KEYES, M. D.

Probably the most striking and important original contribution to medical science was the method of treating syphilis with mercury. Up to that time mercury in such treatment had been found toxic, because usually administered in large doses. Dr. Keyes demonstrated before the International Medical Congress at Philadelphia in 1876 that mercury given in continued small doses in treating syphilis was not a poison but a tonic. His method of treatment was the prevalent one in this country until supplanted by injections. He was also notable as one of the first prostatectomists. Fuller, together with McGill, Fryer and Squier, one of the originators of suprapubic prostatectomy, began working along this line and wrote papers on the subject while he was an assistant in Dr. Keyes's office, and so reflects many of the latter's views.

Dr. Keyes was the author of a number of important works on genitourinary diseases. Beginning his medical career as assistant to Dr. William H. Van Buren, son in law and successor to Dr. Valentine Mott, he collaborated with the former in writing the well known textbook on genitourinary diseases and syphilis, first published by Appleton in 1874. Revised editions of this work appeared after Dr. Van Buren's death under the name of Dr. Keyes alone and also that of his son, Dr. Edward Loughborough Keyes, of New York City. This is still a classical textbook in medical schools and hospitals. Among other works by Dr. Keyes are *The Tonic Treatment of Syphilis, Some Fallacies Concerning Syphilis,* a brief but brilliant guide to treatment, and *Venereal Diseases,* subsequently issued under the joint authorship of Keyes and Chetwood. He was also the author of papers and articles on these subjects and on suprapubic prostatectomy, stricture, urinary fever, and stone.

Dr. Keyes was the founder and first president of the American Association of Genitourinary Surgeons, and at one time vice-president of the New York Academy of Medicine. He was a member of the International Dermatological Society and of the Association Française d'Urologie. Knighthood in the Order of St. Gregory was conferred upon him by Pope Pius X. He was a trustee of the Roman Catholic Church and Orphan Asylum, and served as director of the Columbia Trust Company and of the Fidelity Bank. His oratorical ability was attested by the fact that he was chosen to speak at the opening of the Forty-Third Street building of the New York Academy of Medicine and of the Brady Urological Institute at Johns Hopkins University, Baltimore.

An outstanding fact in Dr. Keyes's medical career was that a great many of his studies and scientific investigations were perfected while he was still a very young man.

Perhaps the dominant characteristic of his personality was his broad humanity. As teacher and practitioner he always emphasized the phase of personal relationship. His clientele included patients from all stations of life, to all of whom he gave of his best with unfailing interest, and sometimes with neglect of material advantages. A supreme honesty and a delightful sense of humor were other qualities that help to explain his many lifelong friends, and the honor, esteem, and admiration in which he was held by the members of the medical profession, to whom his death comes as a great and much deplored loss.

News Items.

New York Physicians' Association Election.—Dr. Charles A. Spivacke was elected president; Dr. Jacob Braun, first vice-president; Dr. Leopold Marcus, second vice-president; Dr. Aaron Brown, treasurer; Dr. Joseph Ziporkes, secretary, and Dr. Max Soletsky, recording secretary.

Dr. Chevalier Jackson Operates on Infant.—Dr. Chevalier Jackson was the surgeon who successfully removed a tack from the lung cavity of an eight months old baby. Dr. Jackson performed the operation without the use of an anesthetic. The tack was removed by means of the bronchoscope and forceps.

Fifth Harvey Lecture.—Dr. Evarts A. Graham, professor of surgery, Washington University, School of Medicine, will deliver the fifth Harvey Society lecture at the New York Academy of Medicine, on Saturday evening, February 9, 1924. His subject will be Alterations of Intrapleural Pressure and their Significance.

Italian Radiological Congress Head.—The fifth Italian radiological congress was held at Palermo, October 18-21, 1923, at the Palermo University. Prof. G. Scaduto presided. Reports were read by Prof. Gortan of Triest on pneumoradiography and Prof. Boidi-Trotti of Turin on radiodiagnosis of urinary apparatus. Prof. Massimiliano Cortan was elected chariman of the April 1925 session to be held at Triest.

Association for the Prevention and Relief of Heart Disease.—At the annual meeting of the Association for the Prevention and Relief of Heart Disease, held in New York on January 16th, Dr. Nathan E. Brill, Dr. Lewis A. Conner, Dr. B. S. Oppenheimer, Dr. Vernon Munroe and Mrs. A. F. Tiffany, the latter replacing Mrs. L. Blagden, were elected as board of governors for a term of five years. Dr. Haven Emerson was elected president; Dr. Robert H. Halsey, vice-president; Dr. William St. Lawrence, secretary; and Dr. Edwin O. Holter, treasurer.

National Committee for Mental Hygiene Election.—Dr. Frankwood E. Williams was reelected medical director of the National Committee for Mental Hygiene at the annual meeting of the board of directors, held in New York City, on December 28th. The following were elected members of the Executive Committee: Dr. William L. Russell, Dr. Walter E. Fernald, Dr. Stephen P. Duggan, Dr. William A. White, Dr. Charles P. Emerson, Dr. C. Floyd Haviland, Dr. Arthur H. Ruggles, and Mr. Matthew C. Fleming. Dr. William H. Welch, president of the National Committee for Mental Hygiene, presided.

Bellevue Medical School Gets New Gifts.—Dr. Samuel A. Brown, dean of the New York University Medical School, announces $60,700 in donations, $40,000 from the estate of Mrs. Egbert Le Fevre, widow of a former dean of the college. The Le Fevre Deanship Fund also received an anonymous gift of $1,200. An anonymous gift of $11,000 was received for the Medical College dispensary endowment fund. A gift of $7,500 came from Mrs. Bettie Fleischmann Holmes; $2,500 for the New York University campaign fund and $5,000 for work in therapeutics. Mrs. W. K. Vanderbilt gave $1,000 for the cardiac clinic of the Medical College. These gifts, following that of $50,000 from Mrs. Charles M. Sherrill, announced recently, made a total of $110,700 received by the Medical College in the last week. Mrs. Sherrill previously had given $90,000 to be devoted to the Edward N. Gibbs memorial x ray fund.

Personals.—Dr. Walter R. Moore, of St. Joseph, Mo., has been awarded one of the resident and travel scholarships for physicians by the American Child Health Association.

Dr. Georges Portman, of the University of Bordeaux, will lecture in New York, Boston, Philadelphia, Montreal, and Quebec during the winter.

Dr. George David Stewart will continue as president of the New York Academy of Medicine in 1924, continuing his two year term; Dr. Herbert S. Carter has been elected vice-president to serve three years; Dr. D. Bryson Delavan has been made corresponding secretary for three years, and Dr. Seth M. Milliken, treasurer.

Dr. William T. Oppenheimer, chief surgeon of the Chesapeake and Ohio Railroad, was presented with an automobile by fellow members of the association in appreciation of his work.

Medical School Discussed for Porto Rico.—Six representatives of Porto Rico have come to discuss with the officials of Columbia University the establishment of a medical school in Porto Rico as part of the university there.

Health Officer Honored.—Dr. J. D. Dowling, health officer of Birmingham and Jefferson County, was awarded the *Birmingham News* loving cup, under direction of a committee of citizens who declared Dr. Dowling had "accomplished most for his community" during 1923.

Rats Carry Plague Into Russia.—The bubonic plague has leaped over the borders of Asia into extreme Southeastern Europe and is threatening the Astrakhan district, according to the *Moscow Workman's Gazette.* Ninety plague spots have been discovered and a horde of plague infested rats is spreading the epidemic along the Volga. A commission has been created to combat the plague danger.

American Surgeon Wanted in Guatemala.—Rev. James Hayter reports to the Presbyterian Board of Foreign Missions at 156 Fifth Avenue, New York, the need of an American surgeon to volunteer for service at the Guatemala Station, Central America, where the demands upon the hospital have reached such a state that it has been found necessary to restrict the number of major operations performed.

Austrian Soldiers to Aid Medical Profession.—Apparatus of various kinds for the study of the voice and speech, including the arc light, laryngobronchoscope, recording drums, speech recorders, breath recorders and equipment for the study of speech in epilepsy, general paralysis, disseminated sclerosis and other nervous diseases, is part of the equipment mapped out by the Austrian Ministry of War to be made by soldiers who have no other trade in their spare time. They will be taught by competent mechanicians.

Infant Mortality Lessened.—Marked reduction in the infant mortality rate at Thetford Mines, Quebec, following a three years' demonstration by doctors and nurses has led the Provincial Government to make an appropriation of $500,000 to establish a chain of clinics throughout the province. The work at Thetford Mines started with a maternity centre opened by the Metropolitan Life Insurance Company early in 1921. At that time, the infant mortality averaged 95 out of 281 babies born, one baby out of every three. Statistics for 1923 show that only 22 out of 300 babies died during the year.

Institute for Orthopedic and Metabolic Diseases Offers Lectures.—The syllabus of a course of lectures with clinical and laboratory demonstrations to be delivered at 498 West End Avenue, New York City, under the auspices of the Institute for Orthopedic and Metabolic Diseases has been announced for the 1924 session from January to March. The lectures are given on Tuesdays and Thursdays, from 8:30 to 10 p. m. The following physicians will lecture during the session: Henry Keller, M.D., orthopedics; Benjamin Jablons, M.D., metabolism; Louis Faugères Bishop, M.D., cardiology; I. W. Held, M.D., and Harris Weinstein, M.D., gastroenterology; Mark J. Schoenberg, M.D., ophthalmology; Charles Goodman, M.D., and Maximilian Lewson, M.D., surgery; Joseph Coleman, M.D., diseases of nose and throat; E. D. Friedman, M.D., and Marcus Neustaedter, M.D., neurology; Charles Herrman, M.D., pediatrics; C. M. Sampson, M.D., Maj., M. C., U. S. A., physiotherapy; L. T. Le Wald, M.D., röntgenology, and Max Taschman, M.D., tuberculosis.

New Discoveries.—Dr. Manueline of the Pasteur Institute has succeeded in isolating the rabies microbe after years of experimenting, according to his published report. Pasteur, who discovered the antirabies serum, did not succeed in isolating the microbe, his research being interrupted by death. His work was carried on by his disciples at the Paris institute and his theories now receive final confirmation.

Dr. Isaac Fried, of Breslau, says he has discovered the means of ascertaining the sex of a child four months before birth, the French Academy of Medicine reports. The method employed is based upon a Wassermann reaction of the blood. A special committee has been appointed by the Academy, to investigate Dr. Fried's findings.

Dr. A. R. Dochez, of Columbia University College of Physicians and Surgeons, and Dr. Francis G. Blake, professor of medicine at Yale University School of Medicine, announce in the daily press the results of their research of the serum for the cure of scarlet fever. While Dr. Dochez stated there were no grounds for stating the serum was a definite curative agent, he reports success in experiments on animals and in nineteen cases.

Foreign Correspondence.

VIENNA LETTER

(From our own correspondent)

VIENNA, *October 13, 1923*

PSYCHOLOGY OF STARVING PEOPLE

Professor Frank, of Charkov, filled the position of director of a large hospital during the time a terrible famine ravaged the southern part of the Ukraine. In this capacity he had ample opportunity to study the effect of continuous starvation upon the human body and soul. This eminent Russian scientist has described his experiences in an article published in a Russian weekly. The observations of a scientist are recorded in this article and are absolutely authentic.

The famine broke out in Ukraine quite unexpectedly, and it affected several millions of men at once. Epidemics of disease and the famine have, at some places, devastated ten to twelve per cent. of the population. Large villages became quite depopulated, and such large towns as Cherson lost the majority of their population. The famine was most serious in those districts where war, revolution, civil war, and uprisings have ravaged the country. Of course, starvation left a very deep mark on the psyche of the population. In the spiritual life of the starving people Dr. Frank distinguished two stages, one of excitement and one of depression. Naturally these two states could not be sharply distinguished from each other. They presented themselves in different ways according to the individuality and physical structure of the persons affected by famine. The bodily and mental excitement experienced in the first stage of starvation showed some resemblance to the attitude of those under the intoxicating effect of alcohol. In the beginning the body as well as the soul experiences a pleasurable excitement, rejoicing in the eventual receiving of foods, and during this period they feel themselves capable of the greatest effort. The spirit is filled with enthusiasm, and the person becomes exceedingly talkative. The drunkenness, however, continues, and nothing remains but depression, the entire breaking of body and soul, and those fighting with starvation of longer duration become idiotic and bestial. In this stage they are ruled by dark instincts, such as migrating from home. The roads and railway lines leading out from the districts inflicted with famine were crowded with these unfortunates, and most of them did not know where they were, where they were going, and what were their plans. Many of them, who spent their nights on the rails, were crushed by the trains. Many crimes committed by the victims in this stage bore the stamp of absolute aimlessness.

Dr. Frank describes the second stage with terrible realism, on the ground of personal experiences. He writes that religious and moral commands and superstitions are annihilated. There is no family life, no social ties. The most frightful egoism, the utter indifference towards the life of another, even towards the next of kin, also toward impotent old men and children, kill every feeling of responsibility in the starving. One mother has spoken even in the first stage of famine as follows: "I have always to fight with myself, when I have to share the piece of bread, which I intended to consume myself, with my children." A man was found beside the corpse of his elder brother, whom he had killed. The knife was still in his hand, and also a piece of raw meat which he had cut out from the body of his brother. It was an everyday occurrence for children, caught in the act of stealing, to be murdered. Unchecked cruelty dominates people.

Most shocking, however, was the eating of men's flesh—cannibalism. This has been mostly met with in women. In many instances mothers killed their own children and ate their flesh. Owing to the change which has taken place in the minds of the starving men by reason of the circulatory disturbances caused by the want of food, the depression grows to such an extent that human life loses all value for these men, and the other man is a mere object, that they kill in order to preserve their own life. Several mothers, who have eaten the flesh of their own children, confessed to Dr. Frank: "He would have died, too. Thus we have saved at least our lives." Such a declaration from a mother's mouth is proof that she could not be held accountable for her deed, and the state of her mind was unsound. Dr. Frank had occasion to see some of these persons after being cured from starvation, having come to Red Cross hospitals where there was sufficient food. They recovered bodily but not mentally, so that they had to be put in insane asylums. Later on it was but natural that cannibalism led to a regular trade in human flesh. These facts show the degree of apathy and the entire disappearance of human feeling in the last stages of starvation.

Some German journals have republished Dr. Frank's article, and they add to it that the first stage of starvation is already present in Germany, being expressed in a gradual mental excitement. There are journals, too, which give expression to a fear that the second terrible stage of starvation will occur in Germany, with all its dreadful effects.

LONDON LETTER

(From our own correspondent)

LONDON, *December 17, 1923*

TUBERCULOSIS IN CATTLE

Tuberculosis has long been prevalent among British cattle, which may account for the comparative frequency of intestinal tuberculosis in children in this country. Active alarm is being expressed by cattle owners and breeders at the wholesale slaughter of cattle which is taking place at the present time owing to tuberculosis and foot and mouth disease. On December 14th last veterinary officials and representatives of public bodies and veterinary societies from all parts of the United Kingdom, together with representatives from Canada, Australia, and South Africa, met at the Royal Sanitary Institution in London to discuss the question of tuberculosis in cattle, and the desirability of allowing the introduction of breeding heifers from Canada if certified free from tuberculosis. Alderman W. P. Neal, late chairman of the Cattle Markets Committee of the City of London, in opening the discussion stated that the matter

of tuberculosis in cattle was of great importance to everyone in the United Kingdom, because it had been shown by science that the bacilli of tuberculosis from cattle could be transmitted to human beings. That being the case it was idle to anticipate that the disease could be eradicated from human beings until tuberculosis in cattle could be arrested and finally eliminated. It was a matter for some surprise that neither the medical profession nor the veterinary profession had prosecuted research so as to enable them to determine what steps were really necessary either to arrest or eliminate the disease. After a considerable amount of discussion two resolutions were passed. The first advocated an investigation by the Ministry of Agricuture into the spread of tuberculosis among cattle and the second declared that it was desirable to allow the introduction of breeding heifers from Canada, subject to a Government certificate that they were free from tuberculosis.

TUBERCULOSIS SETTLEMENTS

In an emeritus lecture given by Sir Kingston Fowler at the Middlesex Hospital, London, on December 13th last, it was contended that sanatorium treatment was not the failure it was now generally said to be. From the industrial point of view Sir Kingston admitted it was not a success, but where patients had the means to devote sufficient time to the treatment it had remarkable results. He ridiculed the idea that working men after a brief stay in the sanatorium could be discharged to do "light work in the open air," and advocated the formation of village settlements in which patients could be gradually fitted to do work equivalent to that performed by them before their breakdown. Such colonies could not be selfsupporting, but just as a people which would not enforce vaccination must build smallpox hospitals, so a nation which tolerated the existence of slums, the breeding places of tuberculosis, must be prepared to pay for the maintenance of tuberculosis settlements.

SMALLPOX AGAIN PREVALENT

The smallpox situation in this country is once more menacing. A sharp epidemic has occurred in Gloucestershire, and outbreaks have been reported from Derbyshire and Nottinghamshire of a severe type. It is alarmingly instructive to realize that the notifications of smallpox during the past two years have been increasing steadily. This signifies that the disease is regaining its hold on the country, a result foreseen and foretold by those cognizant of the neglect of vaccination throughout the country.

CHILD WELFARE CENTRES

On December 15th last two child welfare centres of the most modern type was opened, one in Shoreditch in the East End of London, and the other in Liverpool. Both form part of the experimental scheme of the Carnegie United Kingdom Trustees, initiated in 1918, and involving altogether a capital cost of £200,000. The principle underlying these centres, as was the case with those recently opened in Birmingham and Motherwell, a suburb of Glasgow, is that mothers and expectant mothers should have a place to which they could go for advice, an institution as different as possible from a hospital. The hospital is for the diagnosis and treatment of disease. The Carnegie centres are intended to be of a preventive character designed to make treatment unnecessary by providing in advance of possible illness, institutions in which the mothers may be taught how to bring healthy children into the world and maintain them in health during infancy and childhood. A main feature of these institutions is the training of health visitors, who are taught how best to advise as to the investigation of bad housing conditions, and how poor mothers may best utilize the scanty resources which they have in the way of furniture, food and clothing.

BRITISH ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE

The date of the next meeting of this association to be held in Toronto next year, was provisionally announced for September 3d to 10th, but has now been changed to August 6th to 12th. The meeting will be under the presidency of Sir David Bruce. Preparations are already in active progress, both in Toronto and in London. The American Association for the Advancement of Science intends to hold a short meeting in Buffalo immediately before that of the British Association in Toronto, and reciprocal arrangements are being made for the admission of members of either association to the meetings of the other.

SCHOOL FOR CRIPPLES

At Chailey, in the heart of Sussex, are the Heritage Craft Schools for Cripples. In these schools some two hundred crippled children of both sexes receive skilful medical treatment, and are trained in useful crafts fitting them to hold their place in the battle of life. These schools were founded in June, 1903, and over eight hundred little cripples have passed through them. A special feature of the remedial treatment given is the sunlight or rather indirect sunlight treatment. The institution is thoroughly equipped with heliotherapeutic lamps by means of which the sun rays are utilized for curative purposes. The results obtained already from this treatment have been highly beneficial and Sir Robert Jones, who is chairman of the board of surgeons at Chailey, is confident of still more wonderful achievements in the near future. Surgeon Commander Murray Levick, R. N., who was associated with the late Captain Scott in the Antarctic, is in charge of the light installation. There has been opened recently in this institution what is known as a song school intended for the training of the choir. Below the song schoolroom there is a cloister which will be used for the open air treatment of the children, so that while the crippled children are lying in their beds in the cloisters they will be able to hear the choir singing in the school above.

COCAINE TRAFFIC CHECKED IN LONDON.

It may be said that the cocaine habit is quite a modern evil in this country at least. It was introduced during the war when it was almost as easy to buy cocaine as a cup of coffee. The habit spread rapidly as the drug was cheap and plentiful. The army authorities and the police made the menace perfectly clear to the Government, and a regulation was passed making it an offense punishable by imprisonment for six months to sell cocaine to any member of His Majesty's forces. It was then discovered that the

drug was being eagerly bought, not only by soldiers and sailors, but also by civilians, both men and women, and the regulation was amended, making it an offense for any unlicensed persons to buy or sell cocaine. More severe restrictive regulations were passed but with no effect and the illicit traffic continued. Undesirable aliens, especially Chinese and colored men, who had access to clubs of a questionable character, trafficked in the drug. The risk was taken because of the enormous profits that could be made out of the sale of cocaine. In Germany, where much of it was procured, it could be bought at the wholesale price of £1 to £5 an ounce and smuggled over to this country with comparative ease, and obviously the infliction of a short term of imprisonment was not likely to deter men who might make big fortunes by the traffic. Consequently the British Government a few months ago passed a new law embodying fresh regulations and increasing the sentence on indictment to ten years penal servitude and a fine of £1,000. It is now an offense to offer to supply cocaine, no matter to whom the offer is made. No one is permitted to export cocaine unless an import license is produced from the Government of the country to which he intends to send it and, of course, no unlicensed person is allowed to import the drug. This act has virtually killed the cocaine traffic in Great Britain.

LATIN AMERICA LETTER

(From our own correspondent)

BALBOA HEIGHTS, C. Z., *December 21, 1923*

OPENING OF THE COLON BRANCH OF SANTO TOMAS HOSPITAL

As noted in a previous letter, the Panamanian government is creating four small hospitals in the interior of the Republic to handle emergency and other cases which cannot or should not be transferred to Santo Tomas Hospital in the city of Panama. In Colon, an old building which has been used in the past as a court and a fire station has been transformed into a good hospital for the care of the sick of the Province of Colon. It is called the Colon Charity Hospital and is under the direction of Dr. Joseph Perez, who is assisted by Dr. Pablo Revesz. Although this hospital has just been opened, its thirty ward beds and eight private room beds are filled and a considerable amount of dispensary work is being done in addition. This has materially lessened the work which the free clinic of the Cristobal Woman's Club has been doing heretofore, and is of very great assistance to the sanitary authorities since the small hospital also acts as a health centre.

ALASTRIM STILL CONTINUES

Apparently the restrictive measures which have been enforced against the mild, atypical smallpox which has been moving up and down the West Indies for the past three or four years have succeeded in doing little in an eradicative way. At present the disease is reported as present in Jamaica, Guadaloupe, Cuba, and Martinique. Dominica claims to be at last free from it and recently held special services in all churches in thanksgiving for the freedom of the island from alastrim. British Honduras is reported as free of alastrim and Lieutenant Colonel H. Basil Newman, C. M. G., M. D., of the London School of Tropical Medicine, who has been conducting a series of scientific researches in and around Belize on behalf of the University of London for the past four months, is quoted as saying: "It seemed as though our expedition had struck an unusually healthy year in British Honduras. In previous years there had been occasional outbreaks of fevers of short duration which did not seem to belong to any of the usual types and it was more particularly to investigate these that our expedition was sent out. But during our visit to Belize there was not the ordinary rainy season which usually heralds such fever outbreaks and there were few cases of these undefined fevers."

CONTAGIOUS AND INFECTIOUS DISEASES REPORTED TO THE CHIEF HEALTH OFFICER OF THE PANAMA CANAL DURING THE MONTH OF NOVEMBER, 1923

	Panama	Colon	Canal Zone	Non Resident	Total
Chickenpox	6	3	9	0	18
Diphtheria	1	1	1	0	3
Dysentery	2	2	0	3	7
Hookworm disease	21	6	6	35	68
Malaria	3	5	72	11	91
Measles	50	9	2	1	62
Meningitis	0	0	1	0	1
Pneumonia	35	6	0	0	41
Smallpox	0	0	0	0	0
Scarlet fever	0	0	0	2	2

Yaws	0	1	0	1	2

MARITIME QUARANTINE CONFERENCE

As noted in the Latin America Letter of November 2, 1923, the President of the Republic of Panama, Dr. Belisario Porras, has planned a conference of the Maritime Quarantine Authorities of the Pacific Coast of South America for the purpose of standardizing quarantine practice and improving its efficiency. The call for the conference has just been issued by the Honorable Dr. Narciso Garay, the Secretary of Foreign Affairs. Delegates will be sent by Chile, Peru, Ecuador, Panama and the Canal Zone. Observers from the United States, Great Britain, France and many other countries will attend the conference and assist in its deliberations. The chairman of the Panama delegation is Dr. Augusto S. Boyd and the Secretary General of the conference is Surgeon William Colby Rucker, U. S. P. H. S., Chief Quarantine Officer of the Panama Canal.

MEDICAL VISITORS TO THE CANAL ZONE

The list of recent distinguished medical visitors to the Canal Zone includes Dr. H. F. McChesney, of the Brooklyn Hospital, and Dr. Harrison Dyer, the entomologist of Washington, D. C., who, with Howard and Knab, is the author of the three volume work on *The Mosquitoes of North and Central America and the West Indies.*

NEW HOSPITAL EQUIPMENT

The Ancon Hospital is installing a complete, modern hydrotherapeutic room. All apparatus is new and will represent only the most approved types. It will be housed in the basement of the administration building. A similar installation is being made at the Corozal Hospital.

Book Reviews

PNEUMOTHORAX

La Pratique du Pneumothorax Therapeutique. Deuxième édition. Par F. Dumarest et P. Brette. Paris: Masson et Cie., 1923.

Artificial pneumothorax has become so important a measure in the treatment of certain chest conditions, particularly in tuberculosis, that it is not surprising to find a large volume in its second edition devoted exclusively to this subject. The new edition of this remarkable book is a volume of 350 pages. The first of the six chapters is devoted to descriptions of the various apparatus that have been constructed, and, as it should be, honor is given to the inventor, Forlanini, by the reproduction of his first apparatus. To the American reviewer it seems regrettable that our own Murphy's work receives virtually no mention. To Murphy, as well as to the Italian inventor, certainly belongs the honor of having done pioneer work. The only time Murphy's name is mentioned is in the very extensive bibliography, the compilation of which, by the way, must have been a considerable task as it occupies thirty pages of the book. One can find enumerated in the bibliography everything that has ever been written on artificial pneumothorax, including the construction of the apparatus needed for the performance of the operation.

The second chapter deals with the technic, indications, contraindications, etc. Two methods of technic, that of Forlanini and that of Küss, are carefully described. In both nitrogen gas is still recommended for the purpose of inflation, while in this country almost all phthisiotherapeutists content themselves by using ordinary atmospheric air sterilized. The next chapter is devoted to the external signs which are observed on the chest when the collapse has been partial or complete, followed by an exceedingly interesting description of the effects of pneumothorax on the neighboring organs. The authors first call attention to the dilatation of the intercostal spaces and the displacing of the mediastinum and the diaphragm. Concerning the compressed area obtained by inflation, they very justly say that the absolute extent of the collapse can only be determined by radiographic examination. Next comes a description of the well known immediate results which may follow the production of an artificial pneumothorax, such as increased cough and dyspnea, all of which, as a rule, subsides after a little while. Under accidents and complications, not including pleural shock, the authors mention a persistent dyspnea and a cyanosis of face and extremities. As rarer accidents, digestive disturbances are mentioned, such as diarrhea and enteritis, and under nervous phenomena a postoperative psychosis is spoken of which would seem a rather rare accident.

In the chapters on indications and contraindications are enumerated the well known conditions under which we are using artificial pneumothorax in this country. Because of the tendency of some enthusiasts to apply artificial pneumothorax as a routine treatment in early cases, it is refreshing to see it stated here that in a mild early form, even going very slowly toward recovery, and in all cases tending to fibrosis, artificial pneumothorax should not be resorted to. On the other hand, the authors recommend artificial pneumothorax in uncontrollable hemorrhages, in cases tending to repeated hemorrhages, and in all rapidly ulcerative septic cases where one side is in fairly good condition. Indications for artificial pneumothorax in nontuberculous conditions are given in abscesses of the lungs, hydatid cysts, pulmonary gangrene, bronchiectasis, bullets and other foreign bodies in the parenchyma of the lung, penetrating thoracic wounds, traumatic hemothorax, in aspergillus and mycosis of the lung, and lastly, in pneumonia. Under contraindications the authors emphasize serious bilateral invasion and the concomitant tuberculous conditions such as advanced laryngeal tuberculosis, diabetes, and sclerotic myocarditis.

This second edition of the book represents the actual status of artificial pneumothorax in France. There are numerous illustrations of the inflation apparatus and accessory instruments, and a number of radiographs showing complete or partial collapses in a number of unusually interesting cases, all of which makes the book very valuable.

MEDICAL YEAR BOOK

The Medical Year Book for 1924. Edited by Charles R. Hewitt. London: William Heinemann, Ltd., 1924.

This is a new departure so far as medical books are concerned. It is a yearly *vade mecum* for the medical profession. It is written and compiled by one who is admirably adapted in every respect for the undertaking. Mr. Hewitt, the author, was for many years librarian of the Royal Society of Medicine, and in this capacity came into contact with members of the medical profession from all parts of the country and necessarily became acquainted with their needs. A book of this description has been wanted for long, its object being, as given in the preface, to provide a handy volume conveniently arranged and classified and intended to serve as a guide to the current activities of the profession in Great Britain. It gives reliable information concerning everything worth knowing of the British medical profession and as such should be immensely useful to the American medical man about to visit Great Britain, and it may be said that its possession would save its owner a vast amount of trouble and inconvenience. As a matter of fact the book would seem to be even more fitted for use by the American and Canadian visitor than by the resident medical practitioner.

It is extremely well arranged and well got up and Mr. Hewitt is to be congratulated upon having achieved the object which he set himself in a most successful manner. In addition to detailed information regarding the medical profession and all pertaining to it, original articles on medical subjects of particular interest have been contributed. Insulin and diabetes is dealt with by Dr. O. F. F. Leyton; Cancer, by Dr. C. Powell White; Principles of Chemotherapy, by Mr. J. G. R. McDonagh, and the Fellowship of Medicine, by Mr. Percy Dunn. The book is especially commended to the notice of American medical men who wish to obtain accurate information of British medical matters.

THE SCALP

Entretiens Dermatologiques. Deuxieme Volume. Maladies Du Cuir Chevelu. Par Dr. R. Sabouraud. Paris: Masson et Cie, 1924.

This is a new book of 272 pages, devoted entirely to diseases of the scalp associated with loss of hair. Sabouraud's reputation in this field is so well known and his knowledge of this branch of dermatology is so comprehensive, that it would seem almost superfluous to do more than mention the titles of the different chapters which he takes up. Every phase of the subject is given in detail, and the book is written in plain and interesting style. Much of it, instead of being couched in stilted, technical fashion, is written more or less in conversational style, and the reader feels that he is participating in a lecture instead of reading a highly technical exposition of the subject.

The book deals chiefly with premature loss of hair, alopecia areata, alopecia associated with congenital syphilis, alopecia attended by thyroid disturbances, and so forth. The various malformations and diseases of the teeth as etiological factors, are considered at length. The last two chapters deal with etiology and treatment. The book is well illustrated with striking half tone photographs on glazed paper.

DIAGNOSIS

Diagnostic Methods. By Herbert Thomas Brooks, A.B., M.D., F.A.C.P. Fourth Edition, with Fifty-two Illustrations. St. Louis, Mo.: C. V. Mosby Company, 1923.

This interesting little volume has been carefully gone over since the last edition, with the result that it has been brought up to date in every particular. Certain tests have been omitted, and much new material has been added. The first chapter takes up history taking and continues through physical examination of the patient into the various laboratory tests that are employed in making a diagnosis. The author confines himself exclusively to the task of describing these various tests briefly yet fully, without expressing any opinion as to their merits. Obviously only those procedures are described, which have withstood the test of time and experience. The volume, therefore, is an extremely useful one, which should be at the elbow of every physician and laboratory worker.

CONSTIPATION

The Conquest of Constipation. By William S. Walsh, M.D., New York: E. P. Dutton & Co., 1923.

In view of the fact that fully twenty per cent. of the population of the entire country suffer from this condition, and that approximately fifty million dollars are spent every year in this country alone for proprietary remedies for constipation, it is surprising indeed to learn from this interesting volume that the disorder can be cured, in nine cases out of ten, without resort to drugs or surgery. The author does not accept the general view that constipation necessarily is harmful. He believes that in most cases the effects are not as serious as is often alleged, and that the symptoms of constipation are not always the results of poisoning.

He deprecates the use of drugs, not only because they are habit forming, but because they are unnecessary. Constipation can be prevented, and even cured, according to the author, by the elimination of worry, due attention to personal hygiene, proper training of the intestine, increased water drinking, active and passive exercise, moderation in eating, adjusted diet, and by a correct posture of the body. All of which reminds one of the classical prescription for making a Welsh rabbit.

A careful study of this work undoubtedly would bring about a much better operation of the bowel movements and with it an improved state of health. Unfortunately, however, living is so complicated and fraught with so many anxieties and duties, that it is probable that constipation will long be with us as the most common of all functional disturbances, and that abused Nature will still require such acceleration as drugs, enemas, and other remedies can provide.

STEINACH

Rejuvenation and the Prolongation of Human Efficiency. Experiences with the Steinach Operation on Man and Animals. By Dr. Paul Kammerer. With an introduction by Dr. Harry Benjamin. Illustrated. New York: Boni & Liveright, 1923.

On the theory that revolutionary discoveries, especially when they concern the course of human life as does Steinach's discovery, cannot be retained as the carefully guarded secret of a limited caste of scientists, and in order that the true facts of this far-reaching discovery may reach the public ungarbled, this distinguished biologist has undertaken to explain in a popular style the present state of rejuvenation possibilities as they are based on Steinach's discovery. Kammerer asks why the human mind, which has learned to master the lightning and the floods, and has made steam and electricity do its bidding, should not eventually succeed in attaining supremacy over its own life? Surely an ambitious program, yet one which does not seem so far from realization to the author.

The work consists of thirty-six chapters, including a clinical supplement, references and an index. The author takes his reader with him along the entire route, beginning with the abstract subject of ageing in general, through the innumerable attempts of the past to retain or restore youth, and finally down to the present rejuvenation work in which he has collaborated to a modest degree with Steinach. The various arguments that have been raised against this method are taken up *seriatim* and discussed freely and broadly, and it must be admitted he has made out a strong case, not only for the basis underlying rejuvenation or prolongation of human efficiency, but also for this particular method of accomplishing this highly desired state.

It is to be regretted that Kammerer did not devote himself to a purely scientific presentation of the subject, leaving to some other writer the task of popularizing it. Coming from so eminent a source, a purely technical presentation of Steinach's work would have established it on a plane commensurate with its importance and with its dignity as a surgicobiological procedure of great value. The volume before us does not carry that sense of conviction which a new and comparatively untried scientific procedure requires to "put it across." Undoubtedly the Steinach operation is of great value in appropriate

cases, as Kammerer so well points out, and it is quite probable that it will become vastly more popular with the passage of time. A number of case reports are quoted in the clinical supplement both of foreign and American origin (Benjamin, Wolbarst, Chetwood), all tending to confirm the author's confidence in the value of the procedure and his optimistic views for its future effect on the race. Several illustrations help to visualize the startling effects of the operation in animals and in man, and it must be admitted that these effects undoubtedly were worth striving for.

As a contribution to the popular literature of the subject of rejuvenation, we cannot but feel that this volume will add dignity and sound learning to a mass of stuff that has been fed to a hungry public by the daily press of a certain tint. It will undoubtedly help to establish Steinach's work on the high plane to which it belongs, stripped of all the claptrap that has been showered upon it and similar procedures by designing charlatans. The book can therefore be commended as a clear, unvarnished statement of the biological processes underlying Steinach's work and the experimental studies that have been made along these lines.

MONOGAMY

A Plea for Monogamy. By Wilfred Lay, Ph.D. New York: Boni & Liveright, 1923.

A onesided newspaperish handling of a most important subject. There are many things contained in this book which experience has shown to be true but most of its value is lost in the overemphasis which is placed upon it. The writer may be likened to a small child who on seeing a train go by will insist that the train is enabled to go because the wheels revolve. There are many other things which make a train go, Mr. Lay, and one should first study the locomotive as well as the cars before attempting to call oneself an authority on such a complex subject. One must study the inside and then the outside and then perhaps venture an hypothesis.

FETISHISM

Der Fetishmus. By William Stekel, M. D. Boston: Richard G. Badger, 1923.

Stekel presents this seventh volume of his series with case histories, his own and others taken from the literature, and with a generous amount of discussion upon the subject. The latter is by no means always convincing in regard to the several things which the author sets out to prove. Clearly as he has set forth the phenomenon of fetishism in the psychoneurotic life, in the "parapathies," he does not convince us that it is so worthy of separate classification as he would make it. He has tried to set it apart from some of the interpretation heretofore given it. This revealed it as a manifestation of the partial libido attachment but left it more plainly as merely part of the general disturbance of the psychosexual development and adjustment. Yet Stekel has aided in the understanding of the phenomenon by his study upon it. He has pointed out its active association with onanistic practice, its close relation to compulsion, in fact its own compulsive nature as well as its frequent manifestation in the compulsive acts of kleptomania or public exhibitionism. He has shown in its origin and its compromise service to the individual its connection with religion. Stekel has given rein here to his own proneness to imaginative explanation which pushes the religious interpretation rather beyond strict scientific bounds. The book however adds much valuable material and at least challenges interpretative interest. As always it acknowledges a worthy practical purpose to reveal more clearly prevailing facts of the psychosexual life which are too little known and still less understood but which are of utmost importance. Stekel addresses himself to those groups in society which have a particular responsibility toward understanding individual difficulties in order to deal with them constructively.

POPULATION PROBLEMS

Mankind at the Crossroads. By Edward M. East. New York: Charles Scribner's Sons, 1923.

Edward M. East, now professor of genetics at Harvard University, began his career as a chemist in the fields of food and agriculture. He later devoted himself to the study of practical plant breeding, and is now an eminent authority on the subject of genetics. Hence, he is well qualified to write on the world's population problems, since he bases his statements and opinions upon a vast amount of careful study and original research.

The background of his book is, of course, biological, as is shown in the first chapter devoted to a discussion of heredity and variation. This is followed by a chapter on the history of the population problem, then he takes up his chief theme—population and the food supply, an aspect which he treats in a manner so brilliant and adequate that it forms his chief contribution. His method of tracing and pointing out the close and vital relation of this question to political, governmental and social problems is masterly. He next discusses our agricultural prospects of the future and whether we can develop a permanent agriculture in this country.

His next chapters, entitled the Rôle of Death in the Drama of Life, the Relation Between Birth Restriction and Public Health, the Declining Birth Rate, the Birth Rate and Social Progress and the Welfare of the Family, are all of special interest to the physician. Professor East's argument that preventive medicine has done little to change the incidence of natural selection in man, and the fact that he contributes practically nothing to the important problem of what causes of death in the present day are racially selective, and how greatly so, will raise storms of controversy. He states that the decided increase in length of life within the last hundred years is not due to any lengthening of the normal life span, but that it is a purely statistical result of keeping the weak and unfit alive longer than they have been able heretofore to survive under less artificial conditions. This means, however, that more persons are able to breed than formerly. This process of helping the weak may result—a rather strange conclusion for an authority on genetics!—in "promoting strength instead of weakness."

The reader feels, upon laying down the volume, that Professor East would have made his points more forceful and significant had he not ridden his

hobby, proper birth control, so fast and furiously throughout the book; however, *Mankind at the Crossroads* is a brilliant work, its faults being more of style and manner than of content, and it is worthy the careful attention of all thinking men and women.

Medicoliterary Notes.

A survey of maternity service recently completed by the New York Nursery and Child's Hospital shows that fifty-seven out of every hundred mothers now give birth to their babies in hospitals.

* * *

Saint Joan, a chronicle play, by Bernard Shaw, the current Theatre Guild production in New York, is probably the outstanding theatrical event of the season in that it combines so many of the requisites of great drama—excellent characterization based on true psychology, lines both interesting and entertaining, delicious bits of Shavian humor, and excellent acting and setting.

* * *

The January number of *Mental Hygiene* has a supplement devoted to book reviews. Among these are: A Study of American Intelligence, by Carl C. Brigham, Ph.D.; Problems in Dynamic Psychology, by Dr. John T. McCurdy; Papers on Psychoanalysis, by Dr. Ernest Jones, and Nursing and Nursing Education in the United States, by the Rockefeller Foundation Committee for the Study of Nursing Education.

* * *

The nearest approach to the absolute zero temperature yet attained was achieved recently by Prof. Kamerlingh Onnes, of the University of Leyden, Holland, in an unsuccessful attempt to solidify liquid helium. Expressed in the terms of physics, the degree reached was 0.82 absolute, which means 272.18 below zero Centigrade, or 458 below Fahrenheit.

* * *

Because of the high cost of wood in Germany, experiments have been made in using other materials for coffins. Probably the most successful of these materials is plaster of Paris, which is light, durable, and more easily handled than caskets of solid wood. Gypsum is often used and is only half as expensive as wood.

* * *

The U. S. Public Health Service is making a study of common colds and influenza and the minor respiratory diseases with a view to gathering data sufficiently inclusive to be of value in prevention of such infections.

* * *

Shoes dyed with solutions containing aniline or nitrobenzene will poison the wearer unless they are allowed to dry for at least twenty-four hours before they are worn, is stated in an article in the *Chemical Bulletin* for November written by Prof. A. S. Lovenhart, of the University of Wisconsin, and C. W. Muehlberger. The person affected becomes blue within a few hours, particularly as to lips and nails, and this is accompanied by nausea, headache and dizziness, and often physical weakness. After the shoes are removed, the effects of the poison gradually disappear, the skin resuming its normal hue after several days.

* * *

Bellevue and allied hospitals have recently issued their twentieth annual report covering the year 1921. The pamphlet of more than one hundred pages is devoted chiefly to statistical data.

* * *

The Evolution of the Present Boston Health Department is described by Stephen L. Maloney, its secretary, in an article in the November issue of the *Monthly Bulletin* of the department.

* * *

In a recent address before the American Psychological Association, Prof. George M. Stratton, of the University of California, stated that exciting a bull by waving a red flag has nothing to do with the red. White angers him more, and green nearly as much as red. The real causes of the agitation are the strangeness of the object, its brightness, and its motion.

* * *

The Blind Bow-Boy, by Carl Van Vechten, certainly wins the prize for much ado about futility. Perhaps that is the moral that adorns the tale—we have a sneaking suspicion that it is, in spite of the statement on the jacket, to the effect that the author has taken an oath that he wrote the book for giving amusement and entertainment only. To show up the inanity and futility of the present day socalled Greenwich Village studio life—although most of the incidents of the story take place within the sacred precincts of Gramercy Park—would be the only excuse and possible justification of publishing such trash, for there is not enough amusement and entertainment in the book—and what there is is not very wholesome—to compensate the normal reader for wading through its trivialities.

* * *

Willa Cather's latest novel, *The Lost Lady,* is an admirable presentation of the type of weak but strongly sexed woman who has married out of gratitude a husband whom she thoroughly admires and upon whom she depends for moral support in all ways except her love life, as is shown by her almost complete demoralization after his death. The picture is remarkably just and true to life, for the author bestows upon her lost lady all the charm, generosity and warmth often found in such women, so that we realize her attractiveness and the reason why she is always able to arouse the interest and sympathy of those with whom she comes in contact, and at the same time shows up the weak and repellant side of her nature which leads her into illicit love affairs, and finally into slatternliness and drunkenness. A vague final glimpse of her, many years later, as the wife of a South American money magnate, does little to relieve the impression that she is still "a lost lady."

Practical Therapeutics

PRESENT STATUS OF RADIOTHERAPY

*With Particular Reference to Intensive X Ray Treatment**

SAMUEL STERN, M. D.,

New York,

Radiotherapist to Mount Sinai Hospital.

Intensive x ray therapy is not a new discovery, but is merely the result of improved technic, due chiefly to the following developments:

IMPROVED APPARATUS

The apparatus essential to the carrying out of this technic must be able to develop at least two hundred thousand volts.

THE USE OF HEAVY FILTERS

Our ultimate aim in therapy has always been to use rays as nearly homogeneous as possible. The rays emanating from an x ray tube are a mixture of various wave lengths. The longest wave lengths, having the least penetrating value, are most easily absorbed by the skin and have very little therapeutic value for deep seated lesions.

This value increases in fairly direct ratio as the wave length of the rays decreases. So in deep therapy it becomes important to filter out as many of the longer wave lengths as possible, keeping in mind that the more we filter out the fewer rays are passing through, and the longer the required exposure to get the proper dose. It has been found that the various metals are pervious to x rays in ratio to their atomic weight. Aluminum, which has been mainly used as a filter, has a low atomic weight and permits a larger percentage of longer wave lengths to pass through than any other metal. So to allow only rays of smaller wave lengths to pass through we must use metals of higher atomic weight, such as copper or zinc. It has been found that for this purpose 0.5 mm. copper or zinc equals about ten or eleven mm. of aluminum. The heavier the filter we use, other things being equal, the larger the percentage of depth dose, so the thickness of the filter to be used will depend to a considerable extent upon the situation of the diseased area to be treated.

The factors which determine the percentage of depth dose are: 1, voltage; the higher the voltage the larger the percentage. 2. Thickness of filter. 3. Distance. The farther the focal distance the larger the percentage of depth dose. For instance, at a focal distance of thirty cm. under certain conditions, the absorption at a depth of ten cm. would be about forty-two per cent.; under the same conditions at a focal distance of fifty cm. it would be about fifty per cent. 4. Size of the port of entry. The larger the port of entry, the greater the percentage of depth dose. This is due to the larger percentage of scattered rays which play a very important rôle in therapy.

LETHAL DOSE

We have reached a much better understanding as to what constitutes the lethal dose, that is, a dose which will destroy or make a certain type of tissue innocuous. We have found this to be for the ordinary types of sarcoma about eighty per cent., measured in the depth. This does not hold good for all varieties. Lymphosarcoma requires less than this, and chondrosarcoma and osteosarcoma much more than this. The lethal dose of carcinoma is from 110 to 120 per cent. The ovarian dose, that is, the dose which will destroy the Graafian follicles and produce an amenorrhea, is about forty per cent.

DEPTH DOSE

Professor Dessauer, of the University of Frankfort, through a number of years of experimentation, succeeded in determining the dose absorbed at various depths under different set conditions. This enables us to determine whether in a given case it is possible to administer the lethal dose to a certain diseased area. It does not necessarily follow that if we can do so we are going to effect a cure, but it does mean that, if we find that the disease is so situated that it is impossible for us to administer a lethal dose, our efforts will be useless. Through the aid of a set of carefully prepared charts, by taking approximate measurements of the depth the lesion is situated, we are enabled to select the number of ports of entry necessary to attack the lesion, and to calculate mathematically the amount to be administered through each field to make up the required dose. In doing this, we must be careful to direct our rays so as not to overexpose healthy tissues, always keeping in mind the hypersensitiveness of various organs, such as the spleen and other glands.

There are three kinds of rays that are chiefly to be considered in therapy. 1. Direct rays. 2. Characteristic rays. These are the rays that are produced in the tissues by the direct rays, and each substance has its own characteristic ray which never changes for that particular substance. 3. Scattered rays. These are the rays that are dispersed from adjoining cells and are scattered back and forth in all directions. As to which of the three plays the most important rôle in therapy, it is difficult to say. We do know that the scattered rays are of much more importance than we ever suspected, and it would not be at all surprising if the future showed that they were really the most important of them all.

ESTIMATING SIZE OF DOSE

As regards measuring the quality and quantity of rays produced by these high voltages, we find that most of the methods used for lower voltages are of no help to us whatever. In fact, the only measure that is of any use is the iontoquantimeter, and the one perfected by Professor Friedrich, of Freiburg, is probably the most serviceable. This instrument in his opinion enables him to measure the exact dose administered, irrespective of filter, penetration, distance or any other detail. One hundred and seventy electrostatic skin units make an erythema dose. This can be kept track of without stopping the apparatus even for an instant, and when this number is reached the operator feels certain that the patient has received the exact dose intended to be given.

*Read at the annual meeting of the American Medical Association, held in St. Louis, Mo., May 25, 1922.

APPARATUS

The apparatus, superficially described, consists of a small (one c. c. capacity) ionization chamber made of aluminum, which is connected with a rubber tubing to a large ionization chamber fitted with a gold leaf electroscope. This is charged and as the rays strike the small ionization chamber the electroscope is gradually discharged and the time carefully noted. Each apparatus is tested to determine how many electrostatic units each discharge represents. These are carefully added up and when the required total is reached, treatment is stopped. There are some inaccuracies due to the selfdischarge of the electroscopes, which must be taken care of. This is done by charging the electroscope to six and then waiting to see how much it will discharge of its own accord during the time that it took for one complete discharge with the ray in operation. We now determine how long it takes to discharge this number of units with the ray, and then multiply this time by the number of times the electroscope has been discharged during the treatment. This amount of ray is added to complete the dose. All this sounds rather complicated, but is really very simple. The small ionization chamber can be left on the skin during the treatment to measure skin dosage, or it can be inserted into the rectum or vagina to measure depth dosage. The carcinoma dose, as measured in the vagina, is 152 electrostatic units. The myoma dose is 100 to 120 skin units to each field or 80 units measured in the vagina. In making measurements in the vagina a permanent horse hoof catheter is kept in the bladder to keep this organ empty.

TECHNIC

As to the technic of application, this depends a great deal upon the nature and the situation of the lesion, and what we are trying to accomplish. In cases of malignancy, where it is essential to administer a large depth dose, we find it necessary to use heavier filters, larger fields, greater distance, and higher voltages. Under these conditions we administer the ray up to the point of toleration, that is, we expect a fairly marked erythema to follow each treatment. The formula that I am using in these cases is 200 K. V. at a distance of 50 cm. large fields 3 ma. current with 1 mm. copper+2 mm. aluminum filter for 4 hours. This is practically always followed by a fairly marked dermatitis which disappears in about a week. In cases where we have to use small fields and for various reasons we must cut down our time of exposure, I use the following formula: 200 K. V. at a distance of 23 cm. with compression, size of fields 6×8 cm., this at a depth of 10 cm. spreads to 11. 5×8. 5 cm. 3 ma. ½ mm. copper+2 mm. aluminum filter for 23 minutes. This is followed by an erythema lasting for about a week and then succeeded by a more or less marked tanning of the skin.

The two formulas I mentioned are practically the extremes. I rarely go above a distance of 50 cm. as this would make the time of exposure impractical and 23 cm. is about as near a focal distance as we can get to the skin. We use various modifications between these extremes, each case determining its own technic. There is a great difference of opinion as to when these treatments may be repeated. Some hold that a full intensive erythema dose should not be repeated within six months. Others advise repeating it every month for four or five successive months. I usually wait about six or eight weeks before repeating a near field treatment, and a much longer time before repeating a far field treatment. In treating benign conditions, we do not go to the point of producing an erythema. We rarely give the full dose at one time, but prefer to divide it over a longer period. In fact, in many of the conditions, such as the leucemias, the administration of a massive dose would be accompanied by a great deal of danger.

Practically each individual ailment has to be treated in a different way, depending upon what we are trying to accomplish. The constitutional disturbances, following some of the more intensive treatments for malignancy, are sometimes very severe. There is a marked individual susceptibility about this, which is rather difficult to understand. I have seen patients who had eight hours of intensive ray within two days, who were very slightly affected, while others, who had one quarter of this dose became very ill. The general condition of the patient does not seem to have any influence upon this. Some of the patients, who had very slight disturbances, had been much weakened by recent major operations. The immediate symptoms usually consist of general malaise, nausea, vomiting, occasionally diarrhea, general restlessness and nervousness. To avoid these symptoms, it is advisable to treat all patients on an empty stomach. At Prof. Lexar's clinic in Freiburg, I saw them give the patients two uzara tablets about one half hour before treatment, and two tablets immediately after the treatment was completed. They affirmed that by doing this they had been able to avoid most of the unpleasant symptoms. I have been doing this for some months and believe that the constitutional disturbances following the treatments have been decidedly less severe. Occasionally, when the patient is much weakened, about three or four weeks after the treatment it is advisable to give an intravenous injection of one c. c. of serum in twenty c. c. of normal saline solution.

VALUE OF X RAY IN MALIGNANCY

While intensive x ray therapy may be used in a number of benign conditions, its chief use is in the treatment of the various types of malignant growths. Among these probably the class that offers the most satisfactory immediate results are the various forms of sarcomata. On my trip abroad last summer, in visiting the various clinics I found almost a universal consensus of opinion that no sarcoma of any type should ever be surgically interfered with. They state that practically every case of sarcoma in which an operation was performed was sooner or later followed by recurrence or metastasis. They think that radiotherapy offers a decidedly better chance to these patients, especially as the lethal dose of sarcoma is only about eighty per cent. which amount can be usually administered without much difficulty. The results in some of these cases are really very gratifying. I treated a number of retroorbital sarcomas with a disappearance of the growth, in several cases now over a period of a number of years. Even before the advent of intensive radiotherapy with the

old technic every now and then we succeeded in getting a most astonishing result.

The scope of my paper does not permit me to describe individual cases, but I should like to report one case that I consider very interesting.

Case.—L. R., a young girl of eleven, was brought to me in the fall of 1916 with the following history: About four months before she came to me she had been operated upon by Dr. B. for a sarcoma of the left ovary. This diagnosis was confirmed by microscopical examination. Shortly after the operation, in fact while she was still in the hospital, there was a recurrence in the left pelvis. This began to increase rapidly, until three months later there was a large palpable mass filling the entire left side of the abdomen from the pelvis to the kidney region. The patient at this time had a great deal of pain, could retain very little food, was very much emaciated, and almost entirely bedridden. Upon the mother's anxious solicitation that something more should be tried, the patient was taken to the Post-Graduate Hospital where Dr. P. performed a laparotomy in the hope that the mass might prove to be removable. He found that this was impossible, so he merely removed a small section for examination, which was again found to be sarcomatous tissue. Some weeks later, in the hope that I might be able to alleviate the pain, which at this time was extremely severe, the patient was brought to me for x ray treatment. The response to this treatment was very prompt. About four months after treatments were begun the mass disappeared entirely, the child began to gain in weight, and there was a complete disappearance of all the symptoms. She had periodical prophylactic treatments for a while, and at the time of writing this paper, five and a half years later, she is apparently in perfect health, normally developed, even to the extent of menstruating regularly, despite the large amount of x ray treatments she had received.

LYMPHOSARCOMA

Some of the most gratifying results we get are in cases of lymphosarcoma. All pathological tissues present various degrees of ray sensibility, but none is more sensitive and more responsive to the action of the ray than lymphosarcoma. After a treatment you can almost see the masses melt away from day to day. I have found that in a glandular mass, where it is not feasible to remove a gland for examination to determine its character, we can very often make a diagnosis by submitting the mass to x ray therapy and watch its behavior. If the diminution is very rapid, it is most likely a lymphosarcoma; if the diminution is somewhat less rapid, it is probably Hodgkin's disease, or lymphatic leucemia; if it yields but much more slowly, tuberculous adenitis; if it does not yield at all, the presumption is that the mass is luetic. During twenty years of radiotherapy work, I have been able to confirm this observation on many and various occasions.

CARCINOMA OF THE BREAST

Carcinoma of the breast and of the uterus make up the two largest fields in which intensive x ray therapy has proved of greatest value. In fact several clinics I visited in Germany last year, viz., Opitz in Freiburg, Seitz in Frankfort, Wintz in Erlangen and a number of others, have practically stopped operating in any of these cases. They assert that taking the cases at random, operable and inoperable, their results have been decidedly better with radiotherapy alone than with operation. I personally make it a rule to accept no operable case for radiotherapy treatment unless for some reason or other operation is contraindicated. I still think that the best method of combating malignancy, if the case is operable, is to give a preoperative x ray treatment, followed in about three weeks with complete surgical removal, and this in turn followed, as soon after operation as is feasible, with a course of prophylactic x ray treatments. I have treated a number of primary cases, in which an operation was refused absolutely, or where, on account of old age, or poor general condition or extensive involvement, an operation was thought to be inadvisable. Many of these patients have done very well indeed, especially the older patients, in whom the carcinoma was of the slowly developing scirrhous type. In a number of these the tumor disappeared, and they are still apparently free from recurrence, some many years after the treatment has been administered, although at that time we were working with decidedly less intensive ray than we have at our command today.

In carcinoma of the breast I use one large far field at a distance of fifty cm. for four hours, covering the breast and the entire front of the chest, and two small near fields, one for the axilla and one for the supraclavicular space. Occasionally I also take a large far field from the back, taking in the entire affected side.

CARCINOMA OF THE UTERUS

There is a marked difference of opinion as to the proper technic to be used in the treatment of carcinoma of the uterus. One school, the chief exponents of which are probably Friedrich of Freiburg and Warnekros of Berlin, advise the use of large far fields, even up to a distance of seventy cm., one field from the front and another through the gluteal region, with two small fields from the sides, if necessary, to administer the full dose. A full erythema dose is given and the treatment not repeated in less than six months. The other school, probably headed by Seitz of Frankfort and Wintz of Erlangen, advise the use of four small fields from the front and three fields from the back. This is repeated in six weeks and again in eight weeks. I have tried both methods, but my treatments were given too recently to be able to draw conclusions.

CANCER OF THE CERVIX

In cancer of the cervix, in addition to x ray therapy, radium may also be applied locally.

CANCER OF THE BLADDER

Cancer of the bladder may also be treated much like that of the uterus. In a case I treated, in which the patient was cystoscoped and a small section removed, which was reported to be a carcinoma, the results were so startling that the surgeon felt that a mistake had been made in the diagnosis.

CANCER OF THE RECTUM

These are divided into three classes. 1. Those that are situated eight to ten cm. distance up the rectum. They are the most favorable and are treated the same as cancer of the uterus. 2. Those that are situated three to eight cm. up the rectum. The results are not so good, as it is difficult to get the required percentage of depth dose to the lesion. 3. Those situated at the anus. Prognosis in these cases is very bad.

In carcinomas, involving other parts of the body, we may get a marked improvement of the symptoms, but rarely anything more than that. Although I have seen patients who had metastatic involvement of the spine, and who were bedridden, suffering excruciating pain, get on their feet and be entirely free of pain, after an intensive treatment. This improvement is still persisting, at the writing of this paper, some months after the treatments.

PREOPERATIVE X RAY TREATMENT

This consists in giving the patients one intensive dose about three weeks before operation. The object of it is to make the carcinomatous cells as inactive as possible, to avoid the dissemination of active cells during the operation. This has been carried out too short a time to make definite conclusions possible, but the evidence so far seems to show that it has decided value.

PROPHYLACTIC X RAY TREATMENTS

These treatments have been carried out for a considerable time now, and the preponderance of evidence seems to show that they are of decided value in reducing the percentage of recurrences. To be effective they must be carried out efficiently and persistently. They are begun as shortly after operation as possible, and are repeated at intervals of two or three months for a period of two or three years after operation.

BENIGN CONDITIONS

As to the treatment of benign conditions with intensive x ray therapy, I cannot possibly begin to go into the question. The scope of this paper will not permit it. It is of great value in the treatment of uterine fibroids, menorrhagias and metrorrhagias. It has enabled us to administer a full ovarian dose and produce a permanent amenorrhea in one treatment. In Professor Lexar's clinic for the past two years they have been treating fresh fractures with so-called irritating doses with most satisfactory results. They have succeeded in reducing the healing time about one half. Usually only one treatment is given, as soon as possible after the fracture has been set. The dose given is about one tenth of an erythema dose. I used this technic in a case of ununited fracture of the ulna with satisfactory results. A similar technic is used in the treatment of tuberculous bones and joints, using even smaller irritating doses, one twentieth to one third of an erythema dose.

There is no doubt that intensive x ray therapy is a decided advance over the old technic, and that through its aid we are able to do a great deal more for our patients than we have been able to do in the past.

40 East Fifty-first Street.

Treatment of Lobar Pneumonia Due to Pneumococcus Infection.—Lewellys F. Barker (*Virginia Medical Monthly,* September, 1923) believes that specific treatment by serum or by optochin or quinine, while unquestionably of some value, is not yet entirely satisfactory. He lays stress on the general, dietetic, hydrotherapeutic and symptomatic treatment. Cough, when dry and unproductive, can be controlled during the day with one quarter grain of codeine and one twelfth grain of heroine in tablet form by mouth, repeated every two to four hours. At night it is well to administer a small dose of morphine hypodermically at nine o'clock; it does not seem right to allow patients to be harassed by a racking cough in acute pneumonia, when it can be safely controlled by these means. When pleuritic pain is severe, if it is not relieved by a flat ice bag or salt solution compresses, a small hypodermic of morphine may be needed. Dyspnea in the early stages may be relieved by venesection of three hundred to five hundred c.c.; in the later stages oxygen may be of real assistance when properly administered, as by the Haldane method, or Meltzer's hollow tongue depressor. Insomnia, in the absence of cough and pain, may be overcome by adalin, luminal, barbital, or a drachm of the mistura chloralis et potassii bromidi composita (N. F.). Abdominal distention may be relieved by turpentine stupes, passage of the rectal tube, or the hypodermic injection of one c.c. of pituitrin.

Suction in the Treatment of Septic Ears.—W. Stuart-Low (*British Medical Journal,* July 14, 1923) states that the simplest method of applying suction to the aural cavity is to attach to the nozzle of a medium sized glass syringe or a larger metal syringe a short length of rubber tubing, which must be inserted into the ear, the piston being drawn out to allow all purulent material to be sucked away. Until the ear is dry this treatment must be repeated with the aid of good reflected light. The use of a motor suction pump, with special fine pointed glass tubes bent in several directions, is still better. These tubes may be inserted, under a good light, into the many recesses of the tympanic cavity, up into the attic, down into the depressed floor of the tympanic recess, and back into the aditus. For acute otitis media following paracentesis tympani, all the pus from the middle ear may be sucked out by inserting a finely pointed tube into the incision of the membrana tympani. This treatment, added to the application of bell shaped dry cups over the mastoid, is continued at intervals of forty-eight hours, a mastoid operation being thereby avoided, provided the treatment is used without delay during the inflammatory and congestive stages. For chronic aural suppuration, suction is employed in the ear, over the vein passing out directly from the lateral sinus; it should be repeated once or twice or even thrice a day for at least one month. This method, when carefully carried out, has, with few exceptions, the effect of avoiding operative treatment. It is the means of clearing the ear of discharge so effectively, that it prepares and secures a clear field for operation, should this be necessary, and prevents the development of the most dangerous complication—septic meningitis.

Abstracts from Current Literature

RESPIRATORY DISEASES

Tuberculosis as an Organic Disease.—E. Löwenstein (*Wiener klinische Wochenschrift,* August 2, 1923) draws the following conclusions: 1. Tubercle bacilli may circulate in the blood even in clinically healthy individuals. 2. The changes in the lungs may be so slight in tuberculosis of the bones and the kidneys as to reveal no pathological signs, but at any rate the pulmonary changes in such metastatic tuberculosis are slight as a rule and not active. 3. The bacillemia always appears a short time after the infection. 4. The fate of the tuberculous infection depends upon whether the first localization of the tuberculosis appears in a sensitive or in an immune organ. In the former case, not only the affected organ is involved, but with a sufficiently long duration of the disease, the metastases in the entire system increase, as like tissues become involved by tuberculosis (sympathetic involvement). Tuberculosis is therefore confined to a single organic system in about ninety per cent. of the cases (for example in the lung, kidney, bones, eye, and skin). 5. If the first focus appears in organs not predisposed to tuberculosis, no disease results and there may even be an increased general resistance; these principles may possibly also apply to other bacteria and antigens.

Digestive Function in Pulmonary Tuberculosis.—J. Gordon Hislop (*Lancet,* August 4, 1923) believes that tuberculosis has an inhibitory effect on the digestive function, the quality and the quantity of the gastric juice depending upon, 1, the degree of the inhibition, and 2, the quality and quantity of the gastric juice prior to the onset of tuberculosis. With hypochlorhydria, the indigestion is never severe and yields to treatment readily as a result of stimulation of the gastric secretion. Hunger pain appearing two or more hours after a meal is the predominant symptom and is temporarily relieved by the ingestion of food. The second type is the more common and the symptoms are flatulence, pain, nausea and vomiting. The intolerance of fats alone or in a mixed diet is the main feature. The treatment consists of keeping the mouth and teeth clean with an acid mouth wash used every night and morning. Diluted nitrohydrochloric acid, in doses of ten to thirty minim, is given before or during each meal. In the presence of signs of dyspepsia an excessive diet should be cut down. Milk should be given in moderation, and the addition of sodium citrate often overcomes the difficulty in the assimilation of moderate or reduced amounts. Mixtures of proteins with fats should be avoided. Meats are better cooked in their own juices. Milk should not be given at a meal in which meat is taken. Fish should not be fried in oil. The fat taken with meat should be crisp. Carbohydrates should be given at meat meals.

Internal Complications Following Tonsillectomy and Apical Resection of the Teeth.—W. Falta and F. Depisch (*Wiener klinische Wochenschrift,* August 16, 1923) observed that in a number of cases of nephritis, endocarditis, arthritis, etc., acute exacerbations of these diseases followed operative interferences on the tonsils and the teeth. These exacerbations may be explained most readily by an introduction of infectious material in the vascular and lymph channels during the operation, even though it must be admitted that another mode of infection may be possible. These findings indicate that such complications should be sought for by careful investigations. If the author's theory is found to be correct the operative technic and subsequent treatment should be subjected to revision from this viewpoint.

Internal Complications Following Tonsillectomy.—Fritz Schlemmer (*Wiener klinische Wochenschrift,* August 16, 1923) endeavors to avoid internal complications following tonsillectomy by the elimination of squeezing manipulations when operating upon infected tonsils. These internal complications arise primarily in a lymphogenic manner and only secondarily by the roundabout way of the circulation via previously infected lymph channels. In all inflammatory processes the regional lymph channels and lymph nodes always become diseased first, which shows that the afferent lymph channels must carry off the infected material, which is previously stored immediately in the lymph nodes. The flow of lymph away from the tonsils travels by way of a dense greatly intercommunicating capillary network, and if a centripetal pressure is made from the pharynx upon the lymph channels which open only in a centripetal fashion, the natural result will be the passive expression of toxic material into this capillary network of the peritonsillar tissue. The squeezing of a tonsil full of bacteria is significant only if it is squeezed while it is still intact with its surroundings. The author never grasps the tonsillar substance but seizes the palatal arch with a single pronged volsellum above the tonsil and dissects the mucosa in the shape of a horseshoe with a scalpel in the usual manner without ever touching the tonsil itself. As soon as the tonsil is dissected out more than half from its muscular surroundings, it can be grasped and drawn forward in the usual manner.

Prophylactic Vaccination Against Acute Tonsillitis.—Arthur L. Bloomfield and Augustus R. Felty (*Bulletin of the Johns Hopkins Hospital,* August, 1923) used ninety student nurses for this experiment. Thirty-three of them were found to be carriers of betahemolytic streptococci, seventeen were vaccinated, and sixteen used as controls. There were fifty-seven noncarriers and eighteen of these received a polyvalent vaccine, prepared from twenty-one strains of betahemolytic streptococcus recently isolated from cases of acute follicular tonsillitis. Three subcutaneous doses of 75, 100 and 125 mm. were given at intervals of one week. No case of tonsillitis occurred in the group of carriers whether vaccinated or unvaccinated. In the group of noncarriers, three of the vaccinated group contracted tonsillitis, as against twelve of the unvaccinated. However, the three cases among the vaccinated were so mild as to be almost subclinical, while all but one in the unvaccinated were severe.

Late Results Following X Ray Treatment of Chronically Infected Tonsils and Adenoids.—Charles A. Waters (*Southern Medical Journal,* October, 1923) gives the technic of this form of treatment, follows the course of the cases, describes the results and the bacteriology, and presents the following conclusions: Röntgenotherapy causes a decrease in the size of chronically infected tonsils and adenoids, particularly in the large cellular gland, less so in those which are small and fibrous. It will not cause the hemolytic streptococcus to disappear permanently from the surface of the crypts of the tonsil, but will cause a small percentage of the palpable glands at the angle of the jaw to disappear. Clinically it gives relief from symptoms, but this may be only temporary. In some cases the objective signs do not disappear after this treatment; that is, the size of the tonsils is unchanged, hemolytic streptococcus is still present, and the glands of the neck are palpable, although subjectively they are well. Generalized use of x rays for treatment of chronically infected tonsils and adenoids is not advisable, but seems to be limited to those cases in which a surgical operation is contraindicated, as by chorea, pulmonary tuberculosis, and cardiac and renal lesions. Waters is of the opinion that after the technic has been perfected the greatest field of usefulness for this form of treatment will be found in children. Children rarely have a chronic infection of the tonsils comparable with that of adults. Their tonsils and adenoids are very cellular and of the type that responds most readily to röntgenotherapy, and their symptoms are largely due to hypertrophy of the lymphoid tissue in the throat and nasopharynx.

Etiology of Phthisis in Old Persons.—Hermann Schlesinger (*Wiener klinische Wochenschrift,* May 10, 1923) emphasizes the fact that pulmonary tuberculosis is not rare in senility. Its site of predilection is the pulmonary apices and the location is frequently determined by previous local injury of the tissue, as by compression of the bronchi, stricture, or carcinoma. Its course is usually chronic. The factors which favor its occufrence are the weakened respiratory and circulatory energy, the rigidity of the thorax, degeneration of the lymph nodes, the weakening of the protective and immunity apparatus of the organism, diabetes, carcinoma, unhygienic conditions, and psychic disorders. A certain immunity acquired in early life, emphysema of the lung and, probably, the polyglobulia peculiar to old age, afford some protection against the development and dissemination of tuberculosis.

Oral Râles.—Alfred Schick (*Wiener klinische Wochenschrift,* May 3, 1923) asserts that he has never observed râles in beginning tuberculosis by auscultation of the mouth; they are found in the presence of cavities and bronchitis. Inasmuch as the cavities may be deep in the tissues, oral auscultation is a useful means of examination for rapid orientation and in determining whether any accessory râles are present, their number and size, and whether the disease is extensive or restricted. In addition to all the other clinical and subjective symptoms the determination whether the tuberculous process is benign or malignant is considerably simplified.

The Streptococcus: The Greatest Menace to Mankind.—Sydney Pern (*Medical Journal of Australia,* November 4, 1922) asserts that we have to consider streptococcus infection in the same light as we do that of syphilis or tuberculosis. It is responsible for seventy per cent. of the sickness in temperate zones. It is capable of involving all tissues of the body which have blood or lymphatic channels entering them. We need to recast our ideas as to the origin of many diseases, such as pernicious anemia, diabetes, disseminated sclerosis, psoriasis, certain forms of epilepsy, and others, looking upon them as invasions of certain tissues by a low grade organism capable of cure by removal of the breeding grounds, provided enough tissue is left to function properly, and he maintains that the streptococcus is capable of filling this rôle.

Composition of the Gases in Artificial Pneumothorax.—Leonard Hill and J. Argyll Campbell (*British Medical Journal,* May 5, 1923) show: 1. That the carbon dioxide percentage in the gases of pneumothorax appears to approximate very rapidly to that of the blood bathing the compressed lung. The volume of gas introduced in carrying out artificial pneumothorax may thus be increased at first, but not more than about six per cent. 2. The oxygen percentage in the gases of the pneumothorax cavity approximates that in the tissues bounding the cavity. As nitrogen diffuses out equally, it makes little difference whether oxygen or air be used for inducing artificial pneumothorax. 3. Pathological fluids and tissues usually cause abnormally high percentages of carbon dioxide. Pathological changes probably lower the oxygen content. 4. Any leakage in the thoracic cavity lowers the carbon dioxide percentage, but increases the oxygen percentage in the imprisoned gas.

Value of Radium in the Treatment of Lupus.—H. Baumgartner (*Schweizerische medizinische Wochenschrift,* August 16, 1923) states that, aside from the more prompt effect, radium therapy is preferable to operative methods, for the additional reason that radium destroys only diseased tissue and leaves the healthy mucosa intact. Naturally, the radium must not be left *in situ* too long, depending upon the strength of the preparation used, so as to avoid cauterization of the surrounding tissues and even perforation outward or toward the oral cavity. It is also important to see that the preparation of radium should be applied as closely as possible to the diseased area and kept there by means of packing. Radium therapy also has the advantage, as compared with operative methods, of painlessness and of no interference with the patient's occupation. Mesothorium has also been used with success in lupus of the internal parts of the nose. The success of the treatment with radium or mesothorium depends less upon the extent of the lupus than upon the strength of the preparation used and the duration of their application.

Experiences in New York Hospital with the Treatment of Lobar Pneumonia by a Serum Free Solution of Pneumococcus Antibodies.—Lewis A. Connor (*American Journal of the Medical Sciences,* December, 1922) studied the effect of treatment by the intravenous injection of a serum free solution of antibodies of the three fixed types of pneumococci in a series of 116 unselected cases of lobar pneumonia in adults. The death rate for the 116 cases was 14.6 per cent. The exciting organism in thirteen cases was a streptococcus or the Friedländer bacillus; in this group the mortality was 46.1 per cent. Of the remaining cases, ninety were proved to be due to the pneumococcus, and thirteen were regarded as probably due to this organism. Among these 103 patients the death rate was 10.6 per cent. Type IV pneumonias were conspicuous by their high incidence and low mortality (4.1 per cent.). The treatment seemed to have some real curative value in Type I and Type II cases at least, but the nature of the therapeutic effects of the solution is obscure in view of its apparent effectiveness in Type IV cases. The method is free from the disadvantages incident to the injection of large amounts of serum, but it has one serious defect in that the immediate reactions following the injections are often severe and are occasionally dangerous.

PEDIATRICS

Clinical Study of Muscle Tone in Rickets.—J. D. Douglas Galbraith (*British Journal of Children's Diseases,* July-September, 1923) says that the radiographic and clinical pictures in rickets, while showing general agreement, often show marked discrepancies. The variation in calcium metabolism under different conditions so far as one can accept ossification as an index of calcium metabolism, suggests that the disturbance of calcium metabolism may be a concomitant of rickets rather than the primary stage. Emphasis is laid on the condition of the musculature in rickets, and from clinical observations support is given to the view that the disease may involve the muscles as well as the bones. Bad hygienic conditions, by depressing muscle activity, would be strong predisposing factors to the development of rickets.

Investigations on the Serum for Syphilis in Newborn Healthy Infants and Syphilitic Mothers.—P. Esch (*Zentralblatt für Gynäkologie,* May 5, 1923) states that if the serum of newborn infants from nonsyphilitic mothers be examined, sometimes, as is well known, positive Wassermann reactions are found, which occurrence is explained by the fact that during parturition even healthy mothers now and then give positive Wassermann reactions. To explain this complicated condition, the author studied thirty children from mothers with latent and recent syphilis, and he comes to the conclusion that children from healthy mothers are never syphilitic. Children of luetic mothers, if they have not been subjected to intrauterine infection in the typical recognized manner, may become infected by the blood from the umbilical vein which contains spirochetes, and therefore in established or probable syphilis of the mother, a rapid ligation of the umbilical cord is recommended.

Sour Skimmed Milk in the Digestive Disturbances of Infants.—According to E. Hainiss (*Monatsschrift für Kinderheilkunde,* September, 1923) the use of sour skimmed milk is indicated in the following conditions: 1. In infants, which in spite of breast feeding show no or only slight increase in weight and no signs of dyspepsia. 2. In breast fed infants, which, in spite of no signs of acute intestinal disturbance, are nevertheless losing in weight. 3. In disturbances of nutrition from milk, when the administration of malt soup produces no results and the case is probably one of combined disturbances of nutrition from milk and flour. 4. In disturbances of nutrition from flour. 5. In the presence of exudative symptoms. 6. As one element in mixed feeding, but chiefly in marantic infants, in whom the following feeding of farina gruel cooked in sour skimmed milk twice, and soup and vegetables once, seems to act most favorably.

Acidosis and Alkalosis in Children.—Depletion of the alkali reserve, which occurs in diabetic acidosis, is generally believed to be responsible for the development of acid products of the incomplete metabolism of fats, but the analyses of whole blood made by P. J. Cammidge (*British Medical Journal,* August 25, 1923) also compels the consideration of the incompletely utilized protein derivatives. In some cases, defective elimination in the kidneys, as in interstitial nephritis, aggravates the acidosis. Analysis of the feces in many cases reveals an excessive amount of inorganic ash content. This suggests an abnormal excretion of bases through the intestinal walls, which has a tendency to reduce still further the alkali reserve. Consequently, advanced acidosis, in which several of these factors are at work, is difficult to control, especially in children, in whom the metabolism is much less stable than in adults. Comparatively slight dietary changes in diabetic children often produce striking results; the addition of one egg or a dose of codliver oil may result in ketonuria, which disappears rapidly when the offending food is discontinued. An increase in the alkali reserve is probably partially responsible for the symptoms of pyloric stenosis and infantile tetany. Tetany can be produced experimentally in animals by the injection of alkalies. The analyses of the blood in the alkalosis of adults invariably indicate some ductless gland deficiency, which responds to the administration of the suitable endocrine gland extract and calcium by mouth.

Antitoxin in Diphtheria.—E. S. Platou (*Archives of Pediatrics,* September, 1923), in a comparative study of the usual methods of administration with the intraperitoneal method, draws the following conclusion: 1. A new method of administering antitoxin, namely, the intraperitoneal, is suggested for selected cases of diphtheria. 2. For infants and young children, the simplicity of technic in methods other than the intravenous is emphasized. 3. Local discomfort, an annoying factor in the subcutaneous and intramuscular methods, is absent in the intraperitoneal and intravenous methods. 4. General reactions are noted as a possible hazard, greater in the intravenous than in the other methods. 5. Absorption by the intraperitoneal route does not, of course, approach the intravenous where antitoxin is delivered directly into the blood stream. Early absorption of antitoxin, however, as shown by tests on the blood after intraperitoneal injection, is approximately five times greater after intramuscular injection. Within an hour it is more than sufficient to neutralize the circulating toxin in the blood in any case of diptheria. 6. Absorption by the intraperitoneal method is more rapid in infants than in older children. It is among the former that the procedure finds its greatest use. 7. Intraperitoneal administration of antitoxin is a safe and simple procedure. It is particularly applicable in advanced cases where suitable veins for intravenous administration are lacking, and in moderately advanced cases in which intravenous injection is not considered necessary or advisable, but where more rapid absorption is desired than can be obtained by the intramuscular method.

Importance of Early Administration of Intraperitoneal Infusions in Dehydrated Infants.—The experience of D. C. Wharton Smith, 2nd, and Edmund H. Kerper (*Archives of Pediatrics,* September, 1923) would support that of other observers, namely, that infusions of normal salt solution can be given intraperitoneally with a minimum of risk, practically no pain, and rapid absorption. This method is of great value in cases of dehydration where insufficient fluid can be taken by mouth. It is more effective if employed before extensive dehydration has begun. Repeated smaller infusions are probably of more value than larger amounts given less frequently.

Hemorrhages of the Newborn.—The study of a series of two hundred mature infants, by John Norman Cruickshank (*Lancet,* April 28, 1923) revealed the occurrence of more or less hemorrhage in seventy-seven per cent. If craniotomy cases are included the percentage is raised to eighty per cent. The incidence of stillbirth in the various groups of mature and premature infants shows several interesting features: 1. The difference of twenty-five per cent. in the rate for cases showing capillary oozings and petechiæ only. 2. The similar variation (twenty per cent.) in the rate for cases showing meningeal hemorrhage alone. 3. The twenty per cent. excess of stillbirths in the premature infants with meningeal and visceral hemorrhages over the stillbirths in the corresponding group of mature infants. From the examination of such figures it is evident that many infants with quite extensive birth hemorrhages are born alive and survive. In a number of the cases death had occurred from some quite independent condition, such as bronchopneumonia or nephritis, and it is probable that, but for the intervention of such a disease, the child might have survived beyond the period of infancy, with which one is particularly concerned.

Manifestations of Tetany in Children.—The investigations of Walter Pohl (*Monatsschrift für Kinderheilkunde,* September, 1923) confirm the basic fact that in the disease picture of young spasmophilic infants, the spasms appear in the foreground of the symptomatology, whereas in older children the laryngospasms appear more prominent. However, from this fact the conclusion should not be drawn that there are two temporarily different forms of tetany, but the author would rather call attention to the relationship to the frequently demonstrated peculiar excitability of the cerebral cortex of young infants. As a result of this markedly increased excitability of the cerebral cortex, the spasms are found to be predominant as a reaction in spasmophilic children in the first few months of life. Later the spasms become less prominent with advancing age, because the cerebral cortex gradually loses its excessive excitability. Consequently, the laryngospasms become the predominant element in the picture of tetany. However, very young children are subject to laryngospasms during the first four months of life not too rarely (about sixty per cent. of the author's series). It is not correct, therefore, to speak of a laryngospastic late form, as the laryngospasms again become less prominent in the clinical picture of tetanic phenomena during the second year of life.

GENITOURINARY DISEASES

Specificity of the Wildbolz Own Urine Reaction and Its Significance.—Walter Marcus (*Monatsschrift für Kinderheilkunde,* July, 1923) asserts: 1. The Wildbolz own urine reaction is specific. 2. The antigens excreted in the urine are similar to tuberculin and resistant to heat. 3. Positive reactions in definitely negative tuberculous individuals must be attributed to the constitutional factor of the responsive power of the skin. 4. Salt reactions or reactions of an inflammatory character may be avoided by a proper and areful preparation of the urine. 5. The Wildbolz own urine reaction is not a diagnostic aid in the determination of an actively tuberculous process.

Experimental Production of a Fatal Nephritis with a Filterable Virus of Nervous Origin.—C. C. Twort and H. E. Archer (*Lancet,* June 2, 1923) show that a fatal nephritis may result from the action of a filter passing virus in the absence of any other variety of parasite. Such a virus may cause death with urea etention, although the virus was obtained from diseased nervous tissue, and although the portal of entry was by the central nervous system. Cage infection from animal to animal, when the disease concerned is that from which the animal naturally suffers, is frequent, but this is not so in the case of fomites to animal, nor is it so when a heterologous virus is used, although the animal may be susceptible to artificial inoculation of such a heterologous virus. When immunity to a disease due to a filterable virus has become established the lipase content of the blood may be considerably increased, in many other diseases which excite a mononuclear activity, including blood diseases of doubtful etiology, there is a lowering of the lipase content of the blood during the active stage of the disease. Glycerin extracts of normal liver contain about ten times the quantity of lipase as compared with that of the blood serum or that of glycerin extracts of the spleen or lymphatic glands.

Nephroptosis: Its Causation, Symptoms and Radical Cure.—John J. Bell (*British Medical Journal,* May 26, 1923) is convinced that there is a congenital or family defect of shape of the renal pouch, which predisposes to an easy descent of the kidney, and that there is some inherent weakness in the suspensory tissues which disposes them to stretch easily. Furthermore, the paravertebral niches in which the kidneys rest are shallower and more open below in women than in men, explaining the greater frequency in women of nephroptosis than in men. Of the contributory causes, the most important are nutrition and occupation (long standing and weight carrying); those of lesser importance are repeated pregnancies, loss of intraabdominal pressure and renal tumor and calculi. The recumbent position of the patient is not absolutely reliable for examination. There are three ways of examining for nephroptosis: 1. Facing the back of the patient, the thumb is pressed deeply into the back below the last rib, the fingers grasping and compressing the intervening structures until rigidity passes off, when the kidney can be felt to slip suddenly on deep respiration. 2. The patient on a couch in the sitting position, the knees drawn up and body bent slightly forward, the examination being conducted as outlined above. 3. Fat patients are examined on the side with the knees drawn high up. With each method the compression of the anterior wall is commenced over the iliac fossa, gradually ascending.

The direct symptoms include intermittent dull pain in the small of the back, radiating from loin to thigh, increased on exertion. The reflex symptoms include headache, associated with giddiness and disturbance of vision, sometimes with prostration; there may also be symptoms referable to the cardiorespiratory, circulatory, gastrointestinal, urinary, reproductive, nervous and the chromaffin systems, with symptoms of toxemia. Nephropexy is the only available treatment. The author uses the almost vertical incision and divides the lumbar fascia transversely. The capsule is separated thoroughly from the muscles behind and then clipped through deep in, and stripped off the kidney with the contained fat and pushed deep into the wound and left there. Renal adhesions are divided, especially the renocolic ligament. A tongue shaped flap of capsule from the back of the kidney is raised and passed through the external arcuate ligament, drawing the kidney up into position, and the sus-

pension flap is stitched to the capsule below. The flap may be brought over the last rib. In addition, two silkworm gut stitches are passed through the lower portion of the capsule in the former of a letter U, with the free ends brought through the muscle and skin and tied over a pad of gauze. These are left in place for three weeks.

Useful Urinary Finding in the Diagnosis of Hydronephrosis and Pyonephrosis.—Jacob Rosenbloom (*Journal of Laboratory and Clinical Medicine,* June, 1923) reports the finding of globules of fat in the urine in three cases of pyonephrosis and two of hydronephrosis. In one case the fat droplets were found in the urine obtained by catheterization of the diseased kidney, while the catheterized urine from the normal kidney contained no fat.

Bacteriostatic Action of Urine After the Intravenous Administration of Mercurochrome to Normal Rabbits.—J. H. Hill and J. A. C. Colston (*Bulletin of the Johns Hopkins Hospital,* July, 1923) studied the bacteriostatic effect of mercurochrome on rabbits, which received intravenous injections of the drug in the following doses: one, two and one-half, five, and ten mg. to the kg. Inhibitive action was regularly obtained, and it is concluded that the clinical trial of moderate intravenous doses of mercurochrome is justified from the point of view of bacteriostatic action in bacillus coli infections of the urinary tract.

Inorganic Constituents of the Blood in Experimental Nephritis.—W. Denis (*Journal of Biological Chemistry,* June, 1923) produced an acute nephritic condition in rabbits by the administration of uranium nitrate or sodium tartrate. Although in every case but two there was a considerable increase in the nonprotein nitrogen of the blood, no constant retention of any inorganic component was noted, except in the case of the sulphate fraction, in which large increases were found when the dose of uranium was higher. When a less acute condition prevailed, practically no retention of even the sulphate ion could be demonstrated.

Camphoric Acid as a Disinfectant of Urine.—Erich Liebmann (*Schweizerische medizinische Wochenschrift,* July 12, 1923) reports that camphoric acid in doses of three to four grams daily has proved itself to be a valuable remedy in the treatment of acute and chronic cystitis and cystopyelitis. It is just as effective as the more modern urinary disinfectants and often acts when the others fail. Byeffects, such as heartburn, and after large total amounts hematuria and cylindruria, do not occur often. The gastric symptoms are an indication for the cessation of the administration of this remedy. Hematuria and cylindruria may be avoided by restricting the total doses to sixty gm. Although failures occur, they are not common. This remedy ought to be used more often than it has in the past.

Testing for Urobilinogen.—E. Herzfeld (*Schweizerische medizinische Wochenschrift,* October 5, 1922) maintains that the gradual increase of the fluorescence in the test in feces corresponds completely and in the urine it corresponds almost completely with a period of reaction which is necessary to achieve the optimum of intensity and therefore it cannot be taken as proof of the existence of a constantly present chromogen of urobilin. The p-dimethylaminobenzaldehyde test cannot be used as a direct reaction for urobilinogen, inasmuch as it is also constantly produced by pyrrol and indol bodies, which are left behind as a result of their incomplete elimination. There is, therefore, room for doubt as to the existense of urobilinogen as a constantly occurring preliminary step of urobilin. The extremely slight amounts of urobilinogen in the urine should rather be looked upon as a further reduction product, which may perhaps originate in the transition of the urobilin in the blood into the urobilin of the urine through the kidney.

Treatment of Bladder Tumors.—Robin Pearse (*Canadian Medical Association Journal,* September, 1923) says that if satisfactory results are to be obtained immediate cystoscopy is essential in every case of hematuria of unknown origin. Fulguration through the cystoscope is the method of choice for small papillomata, fulguration through the open bladder for large ones. Partial cystectomy is necessary for sessile carcinomata. Radium and x rays should be reserved for inoperable cases and recurrent carcinomata. Some cases are too far advanced for even this treatment. Patients must be reëxamined two months after operation and if free of growth, six months later and again after a further six months.

Excretion of Sugar in the Urine in Health and Disease.—Ludwig Kast, Hilda M. Croll and Victor C. Myers (*Journal of Laboratory and Clinical Medicine,* January, 1923) determined the amount of reducing substance (sugar) in twenty-four hour urine specimens of normal individuals and hospital patients by various methods. By the use of the Benedict and Osterberg method, it was found that there is an increase in the amount of reducing sugar excreted hourly after meals. The daily output of sugar was comparatively constant when the diet contained about the same amount of carbohydrate each day. Twelve normal adults showed from 0.62 to 1.23 gm. of reducing sugar on the average for twenty-four hours. Diabetes mellitus was the only disease in which there was a marked variation from the normal sugar excretion on ordinary diets, and in this disease, under dietary regulations, when the patient is sugar free the amount of sugar excretion is practically normal.

Prevention and Treatment of Chronic Gonococcal Prostatitis.—Kenneth M. Walker (*British Medical Journal,* September 15, 1923) believes that organisms may spread from an infected prostate by way of the lymphatics as well as the blood stream. Chronic prostatitis is almost invariably associated with a certain degree of infection of the vesicles. The differential diagnosis, however, of prostatitis and vesiculitis is important. Massage of the prostate from the rectum is the most important of therapeutic measures. 1. It empties the prostatic follicles of inflammatory products, and thus assists in the drainage of that organ. 2. It brings fresh blood and lymph to structures that are the seat of chronic inflammation, and hastens processes of repair. 3. It drenches the blood stream with antigen and provokes a reaction similar to that produced by the injection of a vaccine. The author does not believe in dilatation of the prostatic urethra by large sized bougies, or by special dilators (Kollman), as these result in traumatization. He is not very enthusiastic about vaccine therapy, especially in those cases in which the prostatic massage produces a reaction, but he does favor the use of sulpharsenol and silver salvarsan in obstinate cases, especially those complicated by rheumatism. The operation of prostatectomy has an unimportant place in the treatment of chronic prostatitis.

Immediate Prognosis in Nephritis.—O. L. V. de Wesselow (*Lancet,* July 28, 1923) calls attention to the fact that with the increasing application of chemical methods to the study of disease, the accuracy of prognosis in nephritis has made considerable advance. Most of the work has been concerned with the question of the retention of the nitrogenous waste products in the blood, and particularly with the urea content of the blood, because of the ease and accuracy with which this can be estimated. However, there can be no doubt that an estimation of the urea content of the blood in cases of severe azotemic nephritis does not necessarily settle the question of the immediate prognosis. An enormously increased blood urea content is not incompatible with recovery in acute cases, and even in chronic types of nephritis, in which the capacity for recovery is necessarily less, a high blood urea content does not imply speedy death. A confident prognosis can, therefore, scarcely be ventured on from an estimation of the blood urea alone, and several estimations at intervals of several days may be necessary to determine the prognosis. The determination of the plasma content in inorganic phosphorus (phosphate) is of considerable value in the determination of the prognosis in azotemic nephritis. Phosphate retention is associated with certain definite chemical changes in the blood, which are apparently of importance in the symptomatology of uremia. The retention of nitrogenous waste products is a useful guide to the degree of renal damage present, but in itself apparently harmless; phosphatic retention, on the other hand, appears to involve certain deleterious results. Though retention of phosphates is undoubtedly associated with impairment of nitrogenous excretion, and though when a series of cases is averaged, it is found that the rise in the plasma phosphate closely corresponds to the degree of urea retention, in individual cases marked differences in the degree of retention of the two bodies occur. There may be a high blood urea with a relatively low plasma phosphate content, and conversely. The cause of these differences in the degree of retention of the two substances in uncertain; the available evidence would appear to suggest that they are the result not so much of variations in excretions as of variations in the diet, and in the demand for phosphorus and nitrogen for anabolic purposes.

Medicolegal Notes.

UNUSUAL CASE REGARDING LIABILITY FOR MEDICAL SERVICES

Under the Massachusetts Workmen's Compensation Act as amended in 1914, it is provided that the insurer shall in unusual cases, in the discretion of the Industrial Accident Board, furnish reasonable medical and hospital services and medicines required after the first two weeks following an injury. Three cases, two for medical services and one for hospital treatment, furnished to injured employees, came before the board, which found that each of them was an "unusual case" within the statute.

1. Paul Rys was injured May 17, 1921, and was treated from May 19 to September 28, always at the doctor's office, except on May 31 and June 1, when one finger and portion of another were amputated. The board found the injury "a very serious one, complicated by unusual conditions, including degeneration of the skin, laceration of the tissues, necrosis of the bone and tissues, and hemorrhage."

2. Horace Will White received an injury to his hand on October 6, 1921, and was treated by a doctor for five weeks, when he was able to return to work. The palm of his left hand was "cut and lacerated and gravel and dirt were ground into it." The wound was infected and blood poisoning set in. There were twenty-nine visits at the doctor's office and two at the patient's house, the treatment consisting of dressing the wound. The services of a specialist were not required.

3. Mark W. Willis broke his right leg on June 19, 1921. While still incapacitated and receiving compensation, "in March, on account of his knee being weak, he fell down and fractured the old fracture," according to his testimony. He was in the hospital from March 31 to May 7, 1922, and the liability of the insurer to pay the hospital bill for this period was in dispute. The board held this to be an unusual case, apparently because of the recurrence of the fracture. There was no medical or other evidence to show how the fracture occurred, beyond the employee's statement that he fell down.

On appeal, the Massachusetts Supreme Judicial Court held that in the case of Paul Rys, the nature of the injury, complicated as it was by the serious condition of the skin, tissues and bone, was such that it could not say that the finding of the board that it was an unusual case was unwarranted. This decree was affirmed.

In the case of Horace Will White it was held that the finding that it was an unusual case was not warranted. The injury was comparatively simple, and after the first surgical treatment it called only for dressings to prevent blood poisoning. The decree in this case was reversed.

In the case of Mark W. Willis, there being nothing to show any causal connection between the original injury and the second fracture, the case was recommitted to the Industrial Accident Board for further hearing on the question of the seriousness of the injury and its relationship to the original accident. Rys's Case, White's Case, Willis's Case (Mass.) 139 N. E. 505.

DIRECTORS OF HOSPITAL ASSOCIATION ENTITLED TO EXPEL MEMBER WITHOUT RECOMMENDATION FROM STAFF

The constitution and bylaws established for the government of the attending staff of physicians and surgeons of a hospital provided that: "Unprofessional and unethical conduct and violation of the rules of this staff shall constitute a cause for expulsion. Any member against whom charges have been preferred shall be notified of such charges, and shall have the opportunity of appearing before the attending staff and the board of directors in joint meetings in his own defense before final action shall be taken. Three fourths of the staff shall be necessary to recommend expulsion of a member." In a mandamus action brought by the partners in a firm of physicians and surgeons against the hospital association to compel their reinstatement as members of the hospital staff, the Wisconsin Supreme Court holds, State vs. La Crosse Lutheran Hospital Ass'n, 193 N. W. 992, that the bylaws do not in any way deprive the board of directors of their power to exclude physicians from practice in the hospital. "They merely operate to give the members of the attending staff a voice in the matter and to clothe them with advisory powers only. The staff may not expel; they may recommend. If they do recommend, the directors may still do as they please about expelling the member, and the board of directors may expel a member without any recommendation from the staff. This is a power lodged in them by the articles of incorporation, and probably one which they could not delegate if they would. The power to manage the affairs of the corporation includes the power to exclude physicians from practicing therein. If the exercise of this power constitutes a breach of contractual relations, the rights of the other party must be enforced in a proceeding to recover damages or to enforce specific performance. Mandamus will not lie."

FEES OF MEDICAL EXPERT WITNESS ATTENDING IN COURT BUT NOT CALLED

In a will contest the trial judge fixed the sum to be taxed for three medical expert witnesses at twenty-five dollars per day each. The case involved the mental competency of the testatrix, but late in the trial that issue was abandoned. Usually expert medical witnesses are asked hypothetical questions, and there is no need of their sitting in court to listen to evidence. These experts, however, were on hand from a distance, and might have been called as witnesses at any time. The Michigan Supreme Court therefore holds, Jones v. Antrim County Judge, 193 N. W. 873, that the contestant of the will, in laying the issue of want of mental capacity, could not complain on being taxed with the cost incurred to meet the issue. It was no objection that they were not sworn as witnesses, and were allowed the extra compensation provided by statute for opinion testimony, the presumption being that the trial judge knew their testimony would be as to matters of opinion.

RIGHT OF APPEAL FROM OHIO STATE MEDICAL BOARD'S ORDER

Section 1276 of the Ohio General Code grants the right of appeal from the action of the State Medical Board refusing to grant, suspending, or revoking a certificate to practice for the causes named in section 1275, but the section does not define the procedure for perfecting such appeal. An applicant for a certificate to practice under the Limited Practice Act, being refused a certificate, attempted to appeal to the Court of Common Pleas, which court dismissed his petition and the dismissal was affirmed by the Court of Appeals. The Ohio Supreme Court holds, Rutledge v. State Medical Board, 140 N. E. 132, that the right of appeal conferred by section 1276 is a substantial right, which does not fail because of the failure to provide the mode of perfecting it. Where a party desires to appeal and files in the Court of Common Pleas of the county of his residence a petition alleging his grievance against the board and demanding a certification of the papers and records in that court, it is held error to dismiss his proceeding without a hearing upon the claim so appealed.

The Importance of a Knowledge of Reflexes in the Diagnosis of Pulmonary Tuberculosis*

F. M. POTTENGER, M.D.,
Monrovia, California

Medical men have long realized that the detection of small tuberculous lesions in the lung and the determination of whether they constituted an active or quiescent process was one of the most difficult diagnostic problems in medicine. With the results of modern treatment before us, which emphasize the necessity of diagnosing tuberculosis early if the patient is to secure the healing of his lesion at a time when he can be restored to usefulness with relatively little impairment of efficiency, it is the urgent duty of the medical profession to apply diligently the knowledge which we possess toward making the early diagnosis of tuberculosis as simple and certain as possible.

It would be doing great injustice to the many earnest, capable scientists who have devoted their lives to the study of tuberculosis not to recognize the great advancement which their contributions have made to the better understanding of the disease and to its earlier recognition; but it likewise would be unfortunate not to recognize that much more still remains to be learned before the clinical disease can be generally diagnosed early.

The ease and certainty with which tuberculosis is diagnosed has been greatly changed through, 1, the discovery of the tubercle bacillus; 2, the application of the various tuberculin tests; 3, the study of immunological reactions; 4, the examination by the x ray, and 5, the improvement in technic of physical examination.

The age through which medicine is now passing has been characterized by the preeminence of laboratory investigation and an unfortunate coincident inactivity in the field of clinical observation. But, valuable as laboratory examinations have proved to be, they must always be subsidiary to the examination of the patient, and be looked upon only as a means of gaining a better understanding of disease by adding the knowledge which they furnish to that gained by clinical observation. Laboratory examinations should always be interpreted in the light of the data obtained by a study of the patient; for it is the departures from normal physiological action which make up the picture of disease.

It is my purpose to describe certain clinical methods of diagnosis which I have personally developed and which I have found very useful in diagnosing pulmonary tuberculosis. Inasmuch as these are based upon a disturbance or exaggeration in the normal pulmonary reflexes, I shall introduce my discussion by a consideration of pulmonary innervation and the principles involved in reflex action.

INNERVATION OF LUNGS

The lungs are supplied by fibres from both the sympathetic and parasympathetic components of the vegetative system of nerves (Fig. 1). The sympathetics arise from the upper five or six thoracic segments of the spinal cord. The parasympathetics are represented by the fibres of the vagus. All reflexes which take place from the lung must be produced by stimuli which arise in the sensory or afferent fibres of these two systems and are carried to the cord and medulla, respectively, where they mediate with other neurons to complete the action.

PRINCIPLES OF REFLEX ACTION

A reflex is an action produced by a motor nerve, the stimulus for which is carried centralward by a sensory nerve. There are three parts to a reflex: 1, the afferent or sensory nerve which receives the stimulus, the receptor; 2, the efferent or motor nerve which effects the action, often called the effector, and 3, the synapse or junction at which point the stimulus is transferred from the receiving to the effecting portion. A reflex (Fig. 2) requires only two neurons for its completion; but it is doubtful whether so simple a reflex often or, even ever occurs. Most reflexes are very complex, some requiring many neurons for their completion: It is through such complex reflexes that correlation of activity takes place in widely separated portions of the body. It is through reflex action that the varied activities of the different and dissimilar organs of the body are moulded into one harmonious whole.

If disturbances in the normal reflexes of the body are observed and the nerve connections through which the reflexes are produced are known, they may be interpreted as symptoms of disease with distinct diagnostic value. Many reflexes have long been recognized in disease but they have rarely been prop-

*Read before the Annual Meeting of the Kansas City Clinical Society, Kansas City, October 8-13, 1923.

Copyright, 1924, by A. R. Elliott Publishing Company.

erly classified and evaluated. It is possible with the present knowledge of visceral neurology to interpret reflex symptoms which result from inflamed viscera with an accuracy and understanding which is surprising.

SOME COMMON REFLEXES IN DISEASE

Many reflexes are well known in clinical medicine, such as asthma caused by nasal irritation, the motor reflexes in the gastrointestinal tract (functional disturbances) resulting from diseases of the gallbladder, appendix and genitourinary organs; the reflex cough from irritation of the external auditory canal; spasm of the muscles of the abdomen when the gallbladder and appendix are inflamed, or when the stomach and intestines are the seat of ulceration.

REFLEXES ORIGINATING IN THE LUNG

There are many reflexes originating in the lung which manifest themselves when the pulmonary tissue is inflamed. The more common ones I have attempted to classify as follows:

REFLEX SYMPTOMS FROM THE LUNG

		Symptoms	Efferent Nerves
Inflammation of lung	Afferent nerves	Hoarseness	Laryngeal nerves
		Laryngeal irritation	Superior laryngeal nerve
		Cough	Laryngeal and nerves to all expiratory muscles with inhibition of nerves to inspiratory muscles
	Afferent through (vagus) Parasympathetics	Inhibition of heart	Motor fibres of cardiac vagus
		Increased muscle tonus and glandular secretion in gastrointestinal canal	Motor fibres of gastric and intestinal parasympathetic vagus
		Flushing of face	Sensory fibres of fifth trigeminus
		Spasm of sternocleidomastoideus and trapezius	Spinal accessorius
		Deviation of tongue from median line	Hypoglossus
		Degeneration of facial muscles	Trigeminus and sacialis
	Afferent through sympathetics	Flushing of ear	Third sensory cervical
		Dilatation of pupil	Motor from Budges center (lower cervical and upper dorsal)
		Spasm of muscles of shoulder girdle and diaphragm	Cervical motor nerves, second to eighth
		Lessened motion of chest wall, partly due to muscles spasm as above	Cervical motor nerves, second to eighth
		Pain above second rib and spine of scapulæ (superficial)	Cervical sensory nerves, particularly third, fourth and fifth
		Pain in muscles of shoulder girdle (deep pain)	Cervical sensory nerves, second to eighth
		Degeneration of skin and subcutaneous tissue above second rib anteriorly and spine of scapulæ	Cervical sensory nerves, third, fourth and fifth
		Degeneration of muscles of shoulder girdle	Cervical sensory and motor, second to eighth

The reflexes recorded in the preceding table are of varying importance in making up the clinical picture of pulmonary disease, but an understanding of the paths through which they are produced adds greatly to our understanding of the manner in which the disease affects various tissues. It has been particularly in the diagnosis of pulmonary tuberculosis that I have found an appreciation of these reflexes to be most helpful, although reflex disturbances are produced in all inflammatory diseases of the pulmonary tissue.

The motor reflex from the lung affects the muscles which are innervated by the cervical segments of the cord. These are the muscles of the shoulder girdle and the crura and central tendon of the diaphragm. While the reflex spasm is found in practically all of the muscles innervated by the cervical segments of the cord, spasm of the following has proved of greatest value in diagnosis (Fig. 3): sternocleidomastoideus; scaleni; pectoralis, major and minor; trapezius; levator anguli scapulæ; rhomboidei; diaphragm (crura and central tendon).

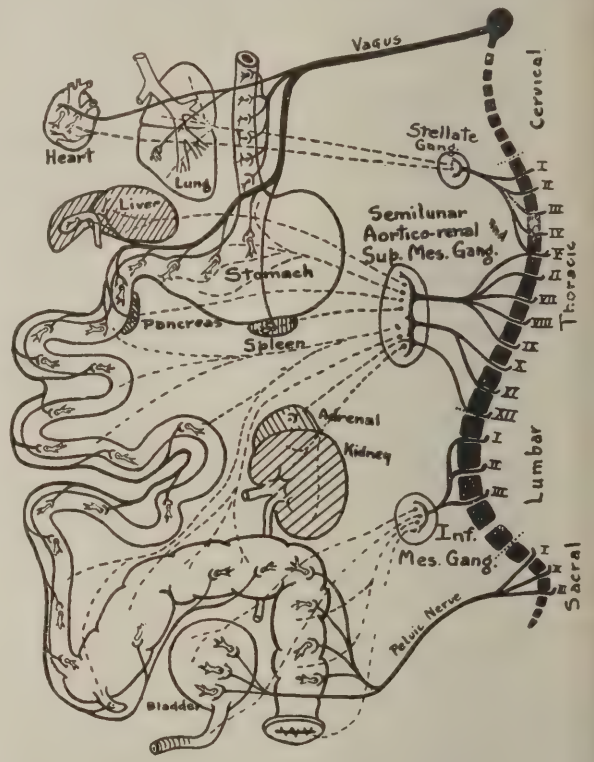

Fig. 1.—Schematic illustration of the double innervation of the enteral system, showing the intimate relationship between the lung and the other important viscera.

The vagus and pelvic nerves (parasympathetic) are represented by solid black lines extending to the organ. The connector neurons of the sympathetics are represented by solid black lines running to the ganglia. The postganglionic fibres running to the viscera are represented by dotted lines. The lung is innervated by both vagus (parasympathetic) and sympathetic fibres from the upper five thoracic segments. The sympathetic motor cells for the lung lie in the stellate ganglia.

In spasm of these muscles in the presence of pulmonary inflammation we are dealing with the same process as in the well recognized rigidity of abdominal muscles in appendicitis, cholecystitis, and ulcer of the stomach. Sherrington suggested the following law governing the segmental visceral reflexes: "For each afferent root there exists in immediate proximity to its own place of entrance in the cord (e. g., in its own segment) a reflex motor path of as low a threshold and of as high potency as any open to it anywhere." Mediation of the reflexes from the lung, however, do not take place in the segments that receive the afferent impulse from the inflamed organ. Instead, the impulses are carried upward by intercalated neurons and mediate with the motor neurons arising in the cervical segments of the cord. This shows how the path of reflexes is determined by

embryological conditions, for the lungs embryologically are given off from segments anteriorly to the heart, aorta and other thoracic viscera, consequently are connected with the skeletal structures by neurons which are innervated most anteriorly.

Increased muscle tension.—The patient must be in the erect position when this reflex is determined. The spasm of the muscles is recognized as an increased tension on palpation and is best appreciated when one lung only is involved, for then the muscles of the two sides can be compared. In cases where both lungs are involved it is necessary to have in one's mind the feel of a normal muscle as a standard of comparison. I find that most of the difficulty experienced by examiners arises from the fact that they do not know the degree of tension to expect in the normal and further fail to realize that it differs greatly with different individuals. Experience, however, will soon furnish the standard.

Limitation of motion of chest wall.—Spasm of the muscles limits the motion of the thoracic wall above by fixation of the sternum through the shortening which results in the sternocleidomastoideus, and the first and second ribs, through the scaleni; and below, through the shortening of the crura of the diaphragm. Limitation of motion may also be caused by other factors, at times, such as acute pleurisy or pleural adhesions, also by loss of pulmonary elasticity or loss of pulmonary tissue. It is commonly observed, also, as an accompaniment of early pulmonary lesions where these latter conditions do not obtain and where the motor reflex in the diaphragm and apical muscles seems to afford the only logical explanation, and it is upon this fact that its diagnostic value rests.

SENSORY AND TROPHIC PHENOMENA OF DIAGNOSTIC VALUE

According to physiological teaching the only true reflex is the one in which a sensory nerve transmits a stimulus to a motor nerve, but from the viewpoint of clinical observation there is a tendency to classify as reflexes all phenomena which are transmitted through an afferent nerve and produced by a second nerve which takes up or transmits the same impulse. So we speak of reflex sensory phenomena, such as the viscerosensory reflex of Mackenzie, and the reflex trophic phenomena in connection with the skin, subcutaneous tissue and muscles, such as I have described when the pulmonary tissue is the seat of such a disease as tuberculosis. I deem it much better to describe these phenomena as reflexes, thus indicating the fact that they are closely related to the motor changes noted in the muscles in their manner of production, rather than to confuse by being more strictly in accord with physiological definition.

SENSORY REFLEX FROM THE LUNG

The sensory disturbance which is best known clinically is pain, but this is only one of many phenomena, such as heat, cold, touch and pressure, which are recognized by the sensory system of the body. These sensations are all recognized by our sensory system and may all be disturbed by conditions which affect sensory neurons.

The skin areas which are supplied by sensory nerves arising from the same cervical segments of the cord that send out motor nerves to the muscles of the shoulder girdle and diaphragm show changes in sensation. This was pointed out by Head many years ago, particularly in reference to the sensation for heat, cold and light touch; but it is of the sensation of pain that I wish particularly to speak.

Acute pain is not as important a symptom in pulmonary disease, unless the pleura also is affected, as it is in pleural and peritoneal involvement and inflammation of the abdominal viscera; nevertheless it is a symptom often found.

Visceral pain is expressed through skeletal sensory

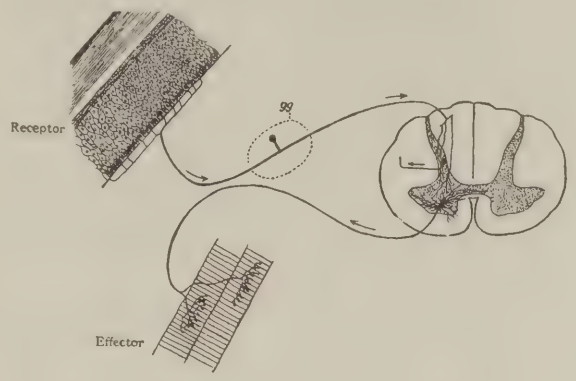

FIG. 2.—A two neuron reflex arc in a vertebrate; gg, ganglion. (Van Gehuchten.)
The receptor or sensory neuron receives the impulse and carries it to or through the ganglion on the posterior root to the cells in the anterior horn of the cord and transmits it to a motor or effector nerve which produces action in another tissue. This is the simplest type of reflex, probably not commonly found in clinical medicine.

nerves and referred to the superficial tissues of the body. The organs themselves do not possess receptors for the ordinary sensory stimuli, such as heat and cold, or the more painful stimuli, such as pinching and pricking, because they are shielded from these stimuli by their protected positions. Receptors for a certain type of sensation are only developed when they are required by the presence of the particular stimulus, and the lung, being a centrally located and protected organ, has never had cause for the development of a delicate pain sense.

The manner in which viscera express these sensory changes which accompany disease is through the more sensitive nerves which supply the surface of the body and which are exposed to and have receptors for all kinds of sensory stimuli. Increased irritability means an easier response. The stimuli passing centralward from the viscera cause an increased irritability in the cells of the afferent neurons over

FIG. 3.—Schematic illustration of pulmonary visceromotor reflex. Lines running between the lung and the spinal cord represent sympathetic nerves. Solid lines carry innervation to the lung. Broken lines carry the impulses from the lung to the cord, where they are transmitted upward in the cord to the cervical spinal motor nerves, which complete the reflex. The muscles involved in this reflex are shown in the cut. The path of the reflex is not as shown in the cut directly from the lung to the cervical portion of the cord, but back to the upper six thoracic segments, thence upward to the cervical portion of the cord by intercalated neurons.

which they pass. This irritability is transmitted to cells lying adjacent to them in the cord which supply sensation to the superficial tissues of the body. Because of the increased irritability of the cells of the sensory skeletal nerves they show altered sensation with a lesser stimulus than normal and the visceral

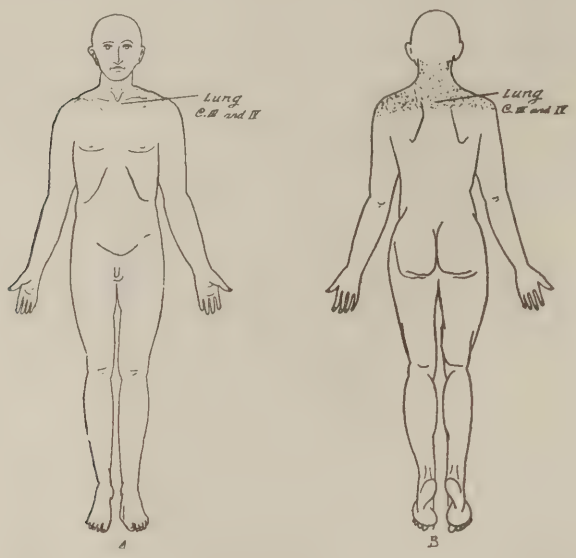

FIG. 4.—Pulmonary viscerosensory reflex; A, anterior view; B, posterior view. The third and fourth cervical sensory zones are involved, the same as are shown in the phrenic sensory reflex from the diaphragm; and on the right side the same as found in the hepatic viscerosensory reflex. Cutaneous pain from the lungs is for the most part, if not wholly, expressed above the second rib (A) and the spine of the scapulæ (B).

sensory effects are transferred to them as being the more highly sensitive nerves, and thus the changes in sensation arising in the viscera are transmitted to the skin and other superficial tissues. In this way we account for the pain expressed on the surface of the body when a viscus is inflamed. Thus, when the appendix is inflamed the surface of the body over the lower right quadrant of the abdomen shows pain to pressure or pinching, and the upper left quadrant when ulcer of the stomach is present.

While acute pain is rarely present as a reflex from the lung, yet there is a certain amount of irritability and uncomfortable sensation, also changes in touch, heat and cold perception which are transmitted to the surface of the body over the zones supplied by the cervical nerves. These areas consist of the tissues covering the neck and upper portion of the chest, above the second rib, anteriorly, and those lying between the occiput and the spine of the scapula posteriorly, as seen in Fig. 4.

Aside from the altered sensations noted in the skin and subcutaneous tissue above the second rib, anteriorly, and the spine of the scapula, posteriorly, there is also a soreness felt, particularly upon pressure, or increased by pressure if otherwise present in the deeper tissues. This reflex may be found in any of the muscles which show the motor reflex from the lung enumerated above, because they all receive their sensory supply from nerves which correspond to the motor nerves which supply them. Soreness over the pectoralis and the trapezius is often complained of by tuberculous patients, whether with or without pressure.

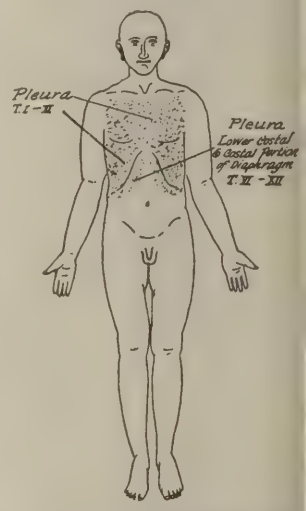

FIG. 5.—Pleural viscerosensory reflex. As shown in figure, pleural pain may occur over any portion of the chest wall; and, if the lower costal pleura and costal portion of the diaphragm are involved, the pain often extends down over the upper surface of the abdomen. It may extend over the entire abdomen.

SENSORY REFLEX FROM THE PLEURA

The sensory reflex from the pleura may be shown as any type of pain from a mild change in sensation to a very sharp excruciating pain. Pleural pain (Fig. 5) contrary to that arising in the lung, is expressed, according to the law of Sherrington, in the same segments of the cord that receive the afferent stimuli from the organ. Consequently, pleural pain may be expressed in any of the intercostal nerves. The pain in pleural involvement is confined fairly closely, as a rule, to the areas over the point of inflammation, except when the costal portion of the diaphragm is involved. Consequently, most pleural pain is expressed over the surface of the chest from the clavicle above to the costal border below. In case of pleural inflammation involving the costal portion of the diaphragm, however, the pain very often extends down over the abdomen. It may extend over any portion of the abdomen and is very often mistaken for the pain caused by inflammation of the underlying abdominal viscera. Not uncommonly are operations for appendicitis, gallbladder disease, and ulceration of the stomach performed upon patients because of a failure to recognize the fact that the pain from the basilar pleurisy may be expressed over the abdomen.

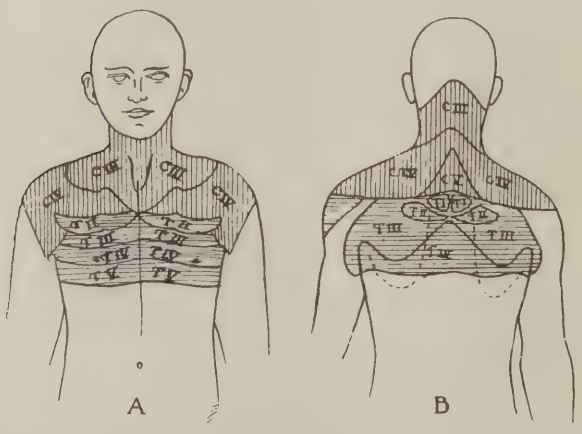

FIG. 6.—A shows by vertical lines the cutaneous and subcutaneous areas which are affected by the pulmonary viscerosensory and viscerotrophic reflexes. Anterior view. This viscerotrophic reflex is shown particularly as a degeneration of the skin and subcutaneous tissue supplied by the third and fourth, and slightly by the fifth cervical sensory roots. It will be seen that anteriorly this includes the tissues of the neck, shoulders, and chest down as far as the second rib.

B shows by vertical lines the cutaneous and subcutaneous areas which are affected by the pulmonary viscerosensory and viscerotrophic reflexes. Posterior viow. This includes the neck, shoulders, and that portion of the chest above the spine of the scapulæ. The interscapular tissues involving T.I, T.II, T.III, and T.IV show the hilus saucer of degeneration. Degeneration in area marked by horizontal lines caused by old pleural involvement.

It is well to bear in mind that the pleural pain may not only be superficial, but also may be expressed in the sensory nerves which supply the deeper structures, particularly the muscles whose sensory neurons are rendered hyperirritable by the afferent pleural stimuli in a manner similar to that mentioned above in connection with the lung.

TROPHIC REFLEXES FROM THE LUNG

The trophic reflex from the lung is expressed in tissues supplied by those neurons which receive and transmit stimuli from the lung to the superficial structures of the body (Fig. 5). Thus it will be seen that the skin areas which show sensory disturbances and the muscles which show motor and sensory disturbances when the lung is inflamed may all be the seat of trophic reflexes, if the inflammation becomes chronic. Just how the trophic reflex is produced is not quite clear. It is possible that it may be due to an actual injury done to the neurons which are responsible for the nutrition of the tissues; or it may be due to a disturbance in the normal blood supply through the sensory nerves which, as is well known, affects the blood supply of superficial tissues. While the motor reflex is a symptom of acute active disease and the sensory reflex may be present either in acute or in chronic processes, atrophy is always the sign of a chronic inflammation.

These trophic reflexes are often evident upon the surface of the body. By inspection alone, or by inspection supplemented by palpation, when the lung has been the seat of an old lesion or is the seat of a chronic inflammatory process, one can see a thinning out of the skin and subcutaneous tissue between the second rib and the angle of the jaw, anteriorly, and between the spinous process of the scapula and the base of the skull, posteriorly (Fig. 6). The muscles which present this atrophy best under the fingers and eye of the clinician, are the sternocleidomastoideus, pectorales, trapezius, and the levator anguli scapulæ.

The degeneration in the skin and subcutaneous tissue shows as a thinning out, a lessening in bulk. In the muscles it shows not only as a thinning and lessening in bulk, but in the long and flat muscles as a change in solidity and rotundity. Instead of the muscle being one solid mass, it often becomes a series of bundles. All the tissues show a loss of elasticity —a feeling of doughiness—upon palpation.

After one has once grasped the neurology which underlies these changes and attained the skill at detecting them, he has at a glance very important suggestions as to the presence or absence of past or present chronic inflammation in the lung. The trophic reflexes combined with the motor reflexes of the lung present accurate signs of the past and present history of disease in the organ.

Airplane Tests of Hay Fever Pollen Density in the Upper Air

WILLIAM SCHEPPEGRELL, A.M., M.D.,
New Orleans, La.,
President, American Hay Fever Prevention Association, Chief Surgeon of Hay Fever and Asthma Clinic, Charity Hospital

In the application of general preventive measures against hay fever, it is important to ascertain the distance to which pollen may be carried by the wind in sufficient numbers to produce hay fever. An important factor in determining this potential area is the altitude at which these pollens may be found in the air.

POTENTIAL AREA OF POLLENS

Our early researches in hay fever were conducted in Orleans Park, my mountain estate near Ashville, N. C., where, in spite of the altitude of 2300 feet, the short ragweed (Ambrosia elatior) is very prevalent (1). When these investigations were transferred to New Orleans, it was found that the short ragweed within the city's limits, was replaced by the long ragweed (Ambrosia trifida). By the middle of September, however, in addition to those of the long ragweed, the pollen of the short ragweed appeared in large numbers on the exposed pollen plates, although the nearest growth of this weed was five miles distant. By the method of direct wind convection, the distance traversed by the pollen appeared inexplicable.

A common cause of early spring hay fever in Austin, Texas, is the mountain cedar (Juniperus sabinoides) whose pollen I first discovered on pollen plates exposed by Dr. Samuel Key of that city. With a view of controlling this form of hay fever, the question was submitted in 1922 as to what distance the male trees, which generate the pollen, should be removed from the city, and my advice was five miles. This was based on an extensive experience in observing the convection of hay fever pollens as observed on pollen plates, but the reason for pollen traversing such a distance could only be surmised at that time.

In order to establish a scientific basis for determining the convection of hay fever pollens, it was found necessary to ascertain the altitude at which they are found in the air. The pollen plates exposed on the tower of a bank building in New Orleans (400 feet) demonstrated that the number of pollens at this height equalled those found on the earth's surface. Pollen plates exposed on the summit of Mount Hope in Orleans Park also showed pollens in numbers differing but little from those exposed at Laurelia Villa, 1000 feet below this level. It was therefore decided to employ some means by which the pollen plates could be exposed to the limit in altitude of pollen infestation.

AIRPLANE TESTS

In the selection of the most practical method of exposing these plates at different altitudes, the airplane was given the preference, as it has many advantages over kites and balloons, as long distances may be covered in a short time, and the process is

directly under control. We were fortunate in securing the cooperation of Mr. B. R. Coad, of the United States Department of Agriculture, in charge of the Delta Laboratory stationed at Tallulah, La., who supervised the flights by which the pollen tests were made.

The airplane tests were made at intervals from June 19th to October 12th, the greatest altitude

Fig. 1.—De Haviland 4B airplane with which the tests of the hay fever pollen density in the upper air were made.

attained being 15,000 feet, and the plates exposed at intervening levels of 1000 feet. The plates used are ordinary microscope slides (one inch by three inches), one side being smeared with a thin film of glycerine or vaseline. The former has the advantage of facilitating the microscopic examination by accepting the Lugol solution for staining, but is easily dried by the great velocity of wind to which the plates are exposed in the airplane, and which is not the case with the vaseline film.

The plates are exposed in a holder expecially constructed for these tests, and is attached to the right side of the rear cockpit (Fig. 1, 2, 3), where they receive the full blast of the propeller. The airplanes used were De Haviland 4B. Extreme care was taken to maintain uniform elevations and a fairly constant flying speed. The propeller was operated at about 1400 to 1450 revolutions a minute during these exposures, the forward speed of the plane being about eighty miles an hour. The exposures were made in the vicinity of Tallulah, but

Fig. 2.—Ready for a test flight.

the flying was almost constantly over cleared or cultivated areas, care being taken to avoid any length of time over timber.

The exposure of the pollen plates from the airplane presents no little difficulty. The operator is greatly cramped for space in the rear cockpit of the plane, and the wind current is so great that everything must be held very tightly. The air at the higher altitudes is also intensely cold. Even at five thousand feet, it is very uncomfortable, and at ten thousand to fifteen thousand feet it is necessary to wear so much clothing that it is difficult to move, and the hands are quickly numbed with the cold if the attempt is made to work without gloves.

PRELIMINARY TEST FLIGHTS

The first tests were made on June 19th, in order to determine the best length of time of exposure. The plates were exposed for thirty seconds, and one and two minutes respectively at elevations of 200, 500 and 1,000 feet. These lengths of time proved inadequate, and, in the next flight, the exposures were made for ten, twenty, and thirty minutes at elevations of 1,000 and 2,000 feet. The twenty minute exposure gave the best results, as the ten minute appeared insufficient and the thirty minute exposure to the great wind velocity caused the glycerine to dry and disappear from the slide. The glycerine film was used in the entire

Fig. 3.—Changing the pollen plate in the specially constructed plate holder.

series, but vaseline was employed in a number of exposures as a check on the tests.

The flights were made while the weather conditions were favorable, and when there had been no rain for at least a week. The wind during the series, as indicated by the anemometer records, varied from two miles to fifteen miles an hour. The time of the plate exposures was twenty minutes.

In the first series of tests, the exposures were made at the various levels during the ascent of the airplane. This proved tedious and difficult, and, in the last two flights of the series, this process was reversed, and the exposures made at 2000 feet intervals during the descent. The first exposure was made at 15,000 feet, the second at 13,000, and thus continued at each odd figure in thousand feet elevations to 1,000 feet. In the following series, the exposures were also made at intervals of 2000 feet, but at the even figures in thousand feet, the two flights thus completing the combined series in intervals of 1,000 feet. This method resulted in expediting the time of each series of tests, so that the duration of each flight was reduced to three and a half hours.

When the exposures had been made, the plates were carefully sealed in special cases, and sent to our New Orleans laboratory, where they were

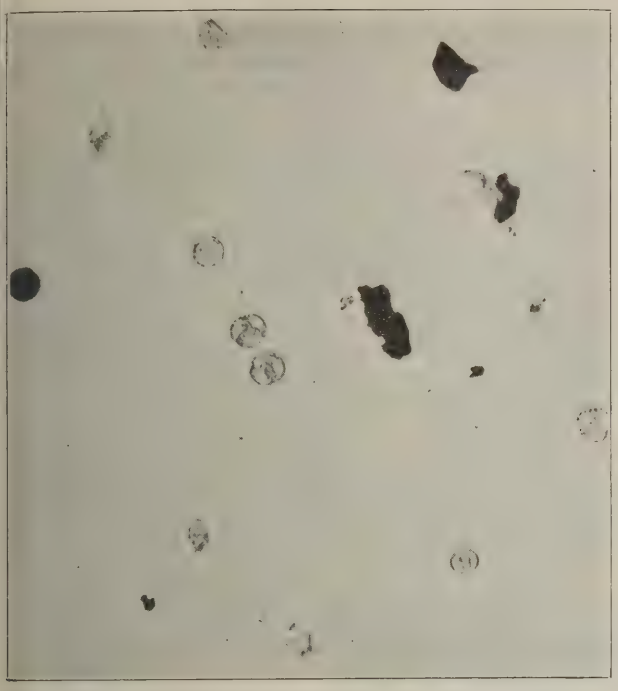

FIG. 4.—Photomicrograph of pollen plate exposed at 2,000 feet elevation, showing ragweed and grass pollen. x 200 diameters.

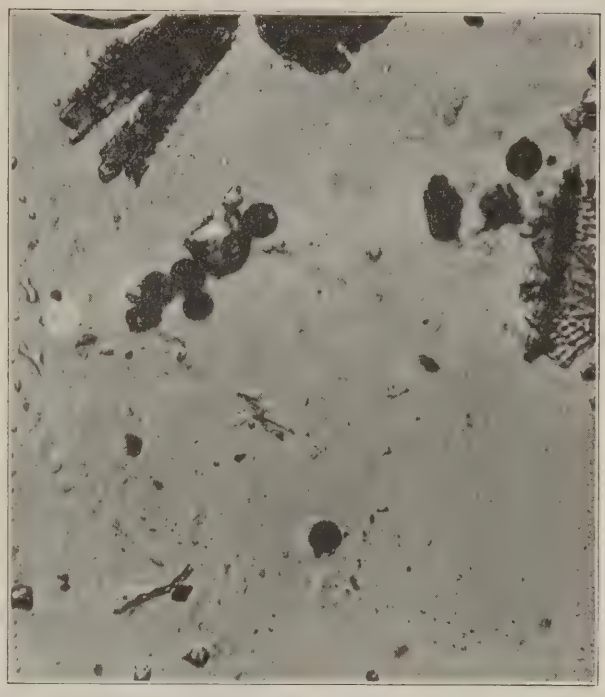

FIG. 5.—Photomicrograph of pollen plate exposed at 3,000 feet elevation, showing ragweed and marsh elder pollen. x 200 diameters.

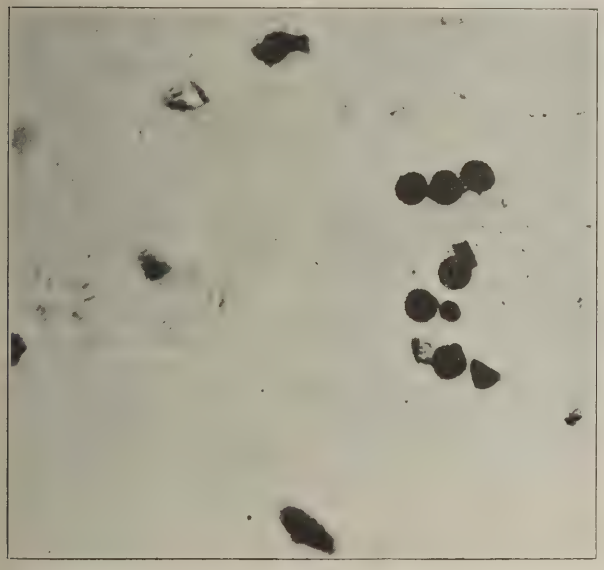

FIG. 6.—Photomicrograph of pollen plate exposed at 4,000 feet elevation, showing short and long ragweed pollen. x 200 diameters.

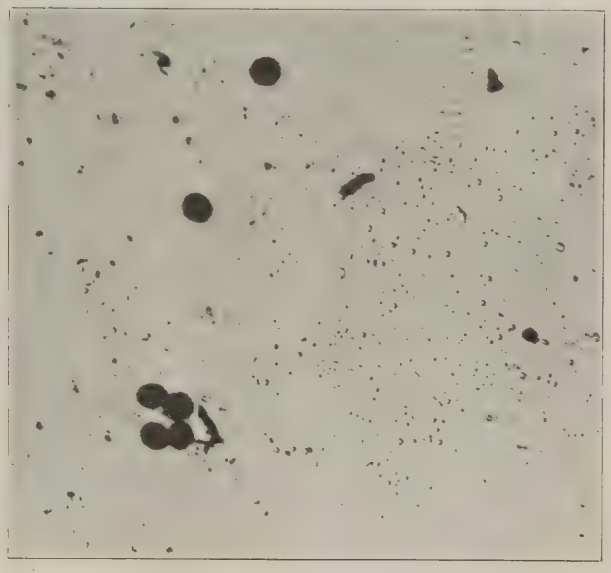

FIG. 7.—Photomicrograph of pollen plate exposed at 5,000 feet elevation, showing long ragweed and grass pollen. x 200 diameters.

stained, inspected and recorded, and, in some cases, photomicrographed.

RESULTS OF TESTS

An analysis of the records of these tests shows that the number of pollens in the air, under favorable conditions, is fairly uniform at altitudes of from 1000 feet to 4000 feet. This is shown by the record of September 24th, which in Louisiana is near the apex of the ragweed pollinating season.

2000 feet elevation, 126 grass pollen, 3096 ragweed pollen, 189 other pollen. Total 3411.

3000 feet elevation, 63 grass pollen, 2346 ragweed pollen, 177 other pollen. Total 3186.

4000 feet elevation, 51 grass pollen, 3192 ragweed pollen, 189 other pollen. Total 3432.

This is also shown in the records of October 11th and 12th, when the pollination of the ragweeds was on the decline.

1000 feet elevation, 84 grass pollen, 708 ragweed pollen, 151 other pollen. Total 943.

2000 feet elevation, 72 grass pollen, 489 ragweed pollen, 180 other pollen. Total 741.

3000 feet elevation, 36 grass pollen, 744 ragweed pollen, 31 other pollen. Total 811.

4000 feet elevation, 90 grass pollen, 756 ragweed pollen, 126 other pollen. Total 972.

At elevations of 5000 feet and 6000 feet there was a uniform decrease in the number of pollens, but the density was still considerable. The average of the records for October 11th and 12th are as follows:

5000 feet elevation, 135 grass pollens, 105 ragweed pollens, 124 other pollens. Total 364.
6000 feet elevation, 102 grass pollens, 258 ragweed pollens, 120 other pollens. Total 580.

Above the altitude of 6,000 feet, there was an abrupt fall in the number of pollens, indicating that the ascending air currents, which had carried the pollens to these heights, had ceased to be operative. From 7,000 feet to 14,000 feet, the diminished number of pollens maintained a fair average, the plates showing about sixty-five pollens at each additional 1,000 feet elevation. At an altitude of 15,000 feet, however, the grass pollen had disappeared, and it was found that there were only eight ragweed pollens adhering to the plate.

VARIETIES OF POLLENS

The ragweed pollen in this report includes both the short and long ragweeds (Ambrosia elatior et trifida), and also the marsh elder (Iva ciliata) which is also a member of the ragweed (Ambrosiaceæ) group (2) and which rivals the ragweeds as a cause of fall hay fever in this section of Louisiana. The two ragweeds and the marsh elder each have spiculated spherical pollen, differing only in size, the short ragweed being fifteen microns, the long ragweed twenty microns and the marsh elder twenty-five microns in diameter.

They also respond equally to the Scheppegrell stain (Lugol solution one part, distilled water one part), appearing a light brown in the field of the microscope. The grass pollens are easily identified, as they appear blue black in this stain (Figs. 4, 5, 6, 7).

The other pollens of this list include those of the careless weed (Amaranthus spinosus) and yellow dock (Rumex crispus), which at that season of the year are not sufficiently common to cause hay fever and of other anemophilous trees and plants, which are negative in hay fever or are of minor importance.

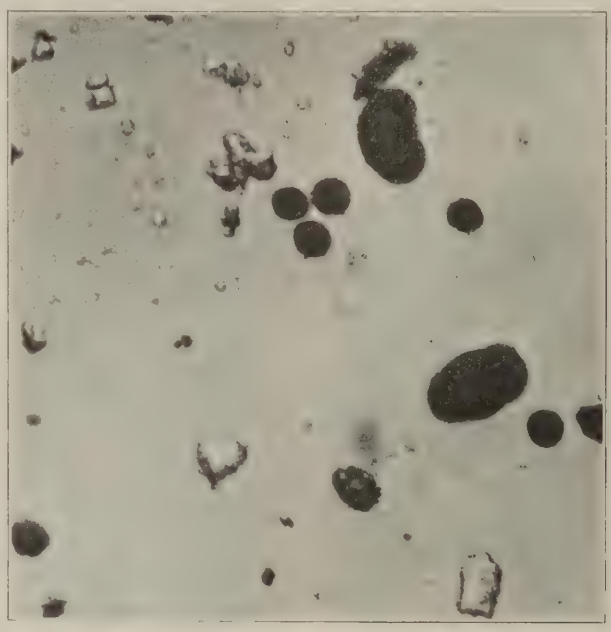

Fig. 8.—Photomicrograph of pollen plate showing pine and grass pollen. x 200 diameters.

PINE TREE POLLENS.

One of these pollens, that of the pine tree, although negative in hay fever, is of interest on account of the great distance which it must have traveled. Although out of season, the pine pollens were found in small but fairly uniform numbers up to an elevation of 13,000 feet. The Delta section of the Louisiana, over which the flying was done, is solely a country of hard woods. The nearest pines are in the neighboring State of Mississippi, a few scattering pines being found about ten miles east of Vicksburg. These pollens must, therefore, have traveled not only vertically to these high altitudes, but also horizontally not less than twenty miles. The pine pollens are provided with two wings or parachutes (Fig. 8) which enable them to traverse distances out of proportion to their size (diameter fifty microns).

POLLENS IN THE UPPER AIR

The reason for the pollens being abundant up to an elevation of 4,000 to 6,000 feet is that they are conveyed upward by the ascending air currents to the height at which the cumulus clouds usually form. When these ascending convective currents cease to be active, the descent of the pollen commences, unless it again meets ascending air currents or is precipitated by rain. If a wind is carrying the pollen horizontally while it is thus falling, the distance which it will be carried is equal to the product of the velocity of the wind multiplied by the time of the fall (3).

The records of the exposed pollen plates do not prove that there is a uniform distribution of pollen in the area in which the flights were made. On the contrary, the pollen clouds change their position in accordance with the atmospheric conditions of the traversed territory. These vary constantly, as demonstrated by the behavior of airplanes over terrain of various characters. Vertical air currents of various velocities are constantly encountered, so that it is necessary to compensate almost continuously for them in operating the control of the plane. Even at considerable elevations, a difference is observed in the behavior of the air over different topographical features. In crossing a comparatively small river, for instance, rising air currents are encountered which bump the plane sharply; while on solid woodland, descending air currents are found which tend to draw the plane downwards. These conditions tend to reverse, moreover, as the day progresses and as different objects absorb or radiate additional heat. In spite of these varying conditions, the results of this series of tests prove that during the active pollinating season of hay fever plants and trees, clouds of pollen conveyed by the ascending air currents are found as high as 4,000 to 6,000 feet above the level of the earth, and that their potential area, unless the pollen is precipitated by rain or descending air currents, easily extends five or more miles from their source, a fact already demonstrated by our exposed plates.

PHYSICAL EFFECTS

The pollen clouds in the upper air explains the persistent presence of pollen at lower levels, as evidenced by the records of our pollen plates. With the exception of periods during rain, and for a short time afterwards, pollens are found in varying numbers during the whole pollinating season of the ragweeds and other hay fever plants and trees.

In our New Orleans laboratory, the pollenometric records show a marked increase of pollen during the prevalence of northerly winds, which was apparently explained by the presence of the greater areas of hay fever weeds north of the city. The increase in the pollen count, however, and a corresponding aggravation of the symptoms in hay fever subjects, was also recorded at our stations in other cities during the prevalence of northerly winds, where the weed distribution is almost uniform in all directions.

As the result of these airplane tests, demonstrating the presence of pollen clouds in the upper air, these phenomena are easily explained. The fall in temperature from the cold winds results in descending air currents, and a corresponding fall in the pollen clouds as long as these maintain, or until the supply of pollen in the air is exhausted.

The existence of these pollen clouds also explains the well known fact that hay fever subjects experience aggravation of their symptoms after sunset, which was formerly difficult to explain. The descending air currents, resulting from the fall of the temperature, allows the descent of increasing numbers of pollen, with proportionate discomfort to hay fever subjects.

SPORES OF FUNGI

In addition to pollen and particles of dust, spores of fungi were fairly common on all plates exposed up to an elevation of 11,000 feet, and some even as high as 13,000 and 15,000 feet. As spores are not responsible for hay fever, no special effort was made to count or identify them, but their presence is of importance as showing the aerial method of distribution of pathogenic germs of plant and animal life. Among the spores of the different genera of pathogenic fungi found on these plates, the most common were those of the conidiophores, alternaria and urediniospores, which are of importance in the study of plant epidemiology investigations.

LEGISLATION

Since hay fever pollens are commonly found in large numbers as high as 6,000 feet, and may thus be carried ten or more miles from their source, the effective control of hay fever by the enactment and enforcement of municipal antiweed ordinances is manifestly insufficient. While such laws are of undoubted assistance, complete relief can be obtained only by legislative cooperation of the various states or of the Federal Government.

SUMMARY

1. Airplanes furnish a practical method of testing hay fever pollen density in the air.

2. During the pollinating season of the grasses, ragweeds and other common hay fever plants, their pollen is found in large numbers in the air up to an altitude of 4,000 feet, and in diminished numbers (sixty-five per cent.) at from 4,000 to 6,000 feet. From this altitude to 15,000 feet the pollens are present but are relatively few in numbers.

3. Unless precipitated by rain or descending air currents, pollen clouds remain in the air during the whole pollinating season of the plants which generate them, the fallen pollen being replaced by new pollen.

4. The existence of these pollen clouds and their change of position due to descending air currents explain the increase of hay fever pollen during the prevalence of cold winds and after sunset.

5. The large potential area of hay fever pollen, resulting from the clouds of pollen in the upper air, demonstrates the necessity of State and Federal laws in the effective control of hay fever in communities.

The Surgical Aspect of Abscess of the Lung*

WILLY MEYER, M.D.,
New York

In hardly any other part of the body are the special branches of medicine and surgery so closely interallied, the borderline so faintly and indistinctly drawn between them as in the treatment of pulmonary abscess.

ETIOLOGY

Suppuration of the lung is due to the same causes as suppuration in any other part of the body, some of which are the following:

1. Traumatism, inclusive of the entrance of a foreign body from within (bronchial tree) or without.
2. Acute or subacute typical inflammation, as it occurs consecutive to the entrance of microbes, such as the pneumococcus, staphylococcus, or streptococcus.
3. Chronic inflammation, tuberculosis and syphilis.
4. New formations: tumors.
5. In exceptional cases we find actinomycosis, hydatid, leprosy, etc., as etiological factors.

If we substitute the term foreign substance for foreign body, then we have at once the various possibilities, namely, solid, semisolid and liquid foreign substances, the latter being represented by mucopus, blood, stomach contents, and infected water. The aspiration of a foreign substance certainly is the principal cause of lung suppuration; the next in order of frequency is embolism. It depends on the virulency of the causative element in either case, whether an acute malignant gangrene will develop.

NOMENCLATURE

At present there exists considerable confusion regarding the nomenclature of this condition. I believe we shall do best—excluding the most fulminant, rapidly progressive suppuration with acute gangrene —to differentiate as follows:

*Read before the New York Academy of Medicine, at its stated meeting on February 1, 1923.

1. The ordinary lung abscess as it usually occurs subsequent to pneumonia or influenza.

2. The typical bronchiectasis, that honeycomb like multilocular diffuse suppuration of one or more lobes of the lung, which, to my mind, probably develops as the result of a congenital malformation in the greatest majority, if not in all of the cases.

3. Bronchiectatic lung abscess, which represents local gangrene.

THERAPY

Early treatment, one might perhaps best term it prophylactic treatment, is of the utmost importance in beginning lung abscess due to aspiration. This prophylactic treatment means bronchoscopy, and that at as early an hour as possible, no matter whether the patient is deathly sick with chills and high fever, continuous cough and foul sputum. It stands to reason that the sooner the infecting foreign substance is removed the better for the patient. In that respect bronchoscopy no doubt is superior to artificial pneumothorax. To my mind the latter, which is also efficient in this class of cases, is to be resorted to only if repeated bronchoscopic suction with intrabronchial treatment fails. Artificial pneumothorax is, after all, surgical interference and in its effect undoubtedly a great deal more complicated than bronchoscopy. I had two beautiful cases of beginning lung suppuration, one following the aspiration of stomach contents during general anesthesia, the other occurring subsequent to tonsillectomy. Both patients were completely healed by means of bronchoscopic aspiration and bronchoscopic aspiration with endobronchial treatment at the hands of the late Dr. Lynah, in conjunction with the specialist at our hospital, Dr. Jordan. We also had at the Lenox Hill Hospital a number of subacute and chronic cases of lung suppuration, all due to aspiration, which were cured by bronchoscopic treatment, four having been under the care of Dr. Jordan and Dr. Kernan, Jr.

As we know, one third of these early cases of lung abscess due to aspiration heal spontaneously. But to say that therefore bronchoscopy is not required would, of course, be an unscientific statement. How can we know who of say thirty such patients will be the fortunate ten who will need no further treatment? Therefore bronchoscopy at the earliest moment possible is clearly indicated in *every* instance of beginning suppuration of the lung due to aspiration. A trained bronchoscopist is the best friend of these patients as well as of the surgeon. For by means of suction promptly applied he lays the foundation for improvement or cure in many cases and absolutely fixates the diagnosis as to which of the lobes is affected.

OPERATION

As regards operation, it seems to me that each of the three subdivisions of subacute and chronic, nonspecific lung suppuration has its special surgical treatment. But before entering upon a discussion of the treatment of nonspecific, subacute, and chronic lung suppuration, let me say a few words on the specific type, tuberculosis and syphilis.

Every patient with abscess of the lung should have a Wassermann test made; if negative in the face of the suspicion of syphilis, primary antispecific régime is clearly indicated, for we all know that a negative Wassermann is not decisive in any case of trouble of this type. I have seen a seemingly hopeless, far advanced case in a man with pulmonary suppuration and four plus Wassermann, who completely recovered with the help of salvarsan, mercury and the iodides. Today he is a prosperous business man.

As to the operation for advanced pulmonary tuberculosis, the thought that operative surgery nowadays may still bring help after expert specialistic internal and hygienic treatment, inclusive of the artificial pneumothorax, has failed, must be most stimulating and encouraging to the ever hopeful tuberculous patient. Formerly hopelessly lost and left to die, two thirds, that means from sixty to seventy per cent. of these patients, if properly selected, can be improved or cured. Surely, a most wonderful advance! There can be no doubt that patients suffering from pulmonary tuberculosis, advanced to a stage where pulmonary and costal pleuræ have become adherent and the artificial pneumothorax is technically impossible, particularly if associated with cavity formation, are clearly borderline cases today. Collapse and compression are the watchwords, and this is made possible by multiple rib resection, from the tenth to the first inclusive, best in stages and under local and regional anesthesia. If necessary unilateral artificial paralysis of the diaphragm by means of phrenicotomy at the neck has to be added, sometimes also loosening of the apex of the lung (apicolysis) with filling of the resulting cavity by transplanted fat or omentum, or the implantation of the pectoral muscle or by heteroplastic material (paraffin). The enforced complete rest plus compression of the lung will produce intensive connective tissue formation, also—for a time at least—chronic local hyperemia, one of the most efficient means of healing tuberculosis.

More recent observations have shown that progressive tuberculosis of the lung in the early stage, with hemoptysis, reacts most favorably to primary radical phrenicotomy, as emphasized by Goetze of Professor Schmieden's clinic at Frankfort. He urgently advises never to let a patient, who was improved by artificial pneumothorax, stop the treatment without having added resection of the phrenic nerve. If this is done, the improvement in all likelihood will be permanent. Otherwise recurrence of the trouble is to be expected in many instances.

Those of us interested have seen most remarkable results in cases of advanced pulmonary tuberculosis by means of operative treatment. One of my patients, hopelessly ill at the time of operation in 1918, is today actively engaged in business down in Texas, selfsupporting and able to climb hills; besides he enjoys the happiness of married life. Even cases of advanced pulmonary tuberculosis complicated with empyema can still be helped by operation.

A closing word on the operative treatment of nonspecific subacute and chronic lung suppuration. We must learn to refine the diagnosis and find out as soon as the patient comes under our care, what type of suppuration we have to deal with. Radiography and bronchoscopy will aid the clinician.

To cure typical bronchiectasis, due in most cases, I believe, to a congenital malformation, as mentioned above, requires lobectomy. Here this radical operation will have its greatest triumphs. Usually only one lobe, mostly the lower, is affected; in exceptional cases it is found bilateral. If the operation is contra-

indicated or not permitted, ligation of the respective branch of the pulmonary artery with or without subsequent extrapleural thoracoplasty may bring relief. Of three patients thus successfully operated on by me—successful, at least so far as the operation was concerned—I have seen one recover almost completely.

The operative treatment of bronchiectatic lung abscess depends on the condition of the patient and other circumstances. If he is not ready to undergo lung resection which still has a mortality of from forty to fifty per cent., a more conservative operative treatment, namely the formation of a lung lip fistula which drains and thoroughly ventilates the existing cavity or cavities either temporarily or permanently —except when the patient later on agrees to have it closed—holds out well founded hopes for a cure. Certainly not all these cases require lobectomy in order to relieve the terrible distress. We should not do lobectomy in every case of bronchiectatic lung abscess any more than we should extirpate every suppurating kidney. Of course, with the lung we may be less conservative, for Nature has endowed our system most liberally with lung tissue. Four big lobes —not counting the small right middle lobe—take care of the proper oxygenation of the blood. We can get along very well with one or two less. The future will have to show whether the following distention and hypertrophy of the remaining lung tissue will allow the surgeon to go still further in his radical work under pressure of pathological conditions. Still, as just said, lobectomy at present is still a dangerous procedure, and as patients of this type coming under our care are usually much reduced, we have to weigh carefully what should best be done, so long as saving the patient's life is the primary consideration. I have seen four of my patients, dangerously ill before, make a most satisfactory recovery with the help of the more conservative intervention: the formation of a temporary or permanent lung lip fistula, which not only drains the lung cavity or cavities, but also the communicating bronchus or bronchi. Two further patients are still under treatment. The lung lip fistula represents a wide canal leading into the focus of the lung and acts like a chimney. In most instances it is wide enough to admit the air required for the maintenance of life, if the patient breathes through the fistula, closing his mouth and compressing his nostrils. The external opening, becoming finally lined with scar tissue all around, usually does not close spontaneously.

It is most encouraging, also, for these patients to know that operative surgery of today holds out to them the hope of great improvement or even cure, if the trouble is not too far advanced and has not yet by aspiration attacked all the lobes of one side or even one of the other in addition.

Here, too, medicine and surgery, the two faithful old sisters, are in close therapeutic cooperation for the benefit of these sorely afflicted.

Lung Abscess*

LUTHER B. MACKENZIE, A.B., M.D.,
New York

Lung abscess is neither rare nor novel, but unpleasantly frequent and all too frequently unpleasant. Previous to ten years ago this condition received relatively scant attention in the literature, and it was in 1912 that Richardson published the first report of a lung abscess following tonsillectomy. Since then an abundant literature has arisen, stimulated undoubtedly by the dire results occasionally seen after tonsil operation. A lung abscess following pneumonia was unfortunate but involved no direct responsibility for the doctor; a lung abscess following tonsillectomy was due to his direct intervention, and the rapidly growing literature is evidence of his appreciation of that responsibility. Suits for damages in these cases are being brought and serve to emphasize further his accountability.

While I am aware that statistics may at times be anything but informing, and sometimes misleading, I hope that these will at least be of some interest. I have gathered together some Bellevue Hospital statistics of both the quick and the dead.

CLINICAL STATISTICS

These cover a period of five years, 1918-1922 inclusive. During this time there were admitted to the hospital in 1918 twenty-two cases of lung abscess with eleven deaths; in 1919, twenty-five cases with eleven deaths; in 1920, twenty-eight cases with fifteen deaths; in 1921, forty-three cases with twelve deaths; and in 1922, fifty-one cases with eighteen deaths. In all 169 cases with sixty-seven deaths, a mortality of about forty per cent. As in the dead house statistics (to be given later), bronchopneumonia was the most frequent cause. Eleven followed tonsillectomy. Some figures from the Massachusetts General Hospital quoted by Whittemore give seventeen out of thirty-two lung abscesses as due to tonsillectomy.

Dr. Isabella Herb, of the Presbyterian Hospital of Chicago, reports that in a total of 12,045 operations on the tonsils, lung abscess developed in only two. It is not stated over what period of time these operations extended but it was probably not under three years. Dr. Bevan, of the same hospital in Chicago, reports twelve cases of lung abscess in three years following tonsillectomy. This illustrates some of the vagaries of medical statistics.

Moore, of Philadelphia, has estimated that in every 2,500 cases of tonsillectomy one lung abscess will develop; Fetterolf places it at one in 780 operations. Whatever the percentage, there can be no doubt that tonsillectomy is a fruitful source.

*Read before the New York Academy of Medicine at its stated meeting, February 1, 1923. (*From the Third Medical Division of Bellevue Hospital.*)

POSTMORTEM STATISTICS

In the past eighteen years (i. e., since complete protocols have been filed) there have occurred in Bellevue Hospital 56,597 deaths. Of these, autopsies have been performed in 8,395, a proportion of one in 6.7. During the past five years (the years in which the clinical data were gathered) there were 17,818 deaths with 2,673 autopsies, a proportion of one in 6.7—a rather striking uniformity. These figures seem to establish that in Bellevue Hospital over somewhat extended periods of time the ratio of autopsy to death is fairly uniform and constant.

Of the 8,395 autopsied in eighteen years, 208 were found to have lung abscess, a proportion of 1 in 40. During the past five years in the 2,673 that came to the postmortem table 86 had lung abscess, a proportion of 1 in 31. Of these 86, five died of abscess following tonsillectomy, a condition not prevailing in the earlier years of these statistics, reducing our proportion to about 1 in 33. It is also to be remembered that these past five years were the years of the influenza epidemic, with the frequent occurrence of lung abscess. Possibly, too, lung abscess is becoming more frequent.

It is a fair estimate, however, that in every forty cases coming to autopsy, one will have a lung abscess; in other words, in every forty deaths, one lung abscess will be found. In the past five years, as above stated, there occurred 17,818 deaths, and as above reckoned (1 in 40) there must have been 445 deaths with lung abscess.

DEATHS FROM LUNG ABSCESS

Viewed from another angle, the ratio of autopsy to death being 1 to 6.7 and there having been 86 autopsies with lung abscess there must have occurred 86×6.7, or 575 deaths with lung abscess, during these five years. From these statistical manipulations it is deduced that during this five year period there were from 445 to 575 deaths with occurrence of lung abscess. Of course this is only an approximation.

There were recognized clinically during this five year period sixty-seven patients dying with lung abscess, a rather striking discrepancy. Many of these unrecognized abscesses occurred during the course of a pneumonia or infective endocarditis or sepsis, death being due to the primary disease and obscuring the lung abscess; in others, the abscesses were small, giving few physical signs and were overlooked, and in still others incorrect diagnoses were made. While statistics may mislead, it seems a fair inference that lung abscess is of quite frequent occurrence, that it is not an unfrequent cause of death, and that it is sometimes overlooked.

ETIOLOGICAL FACTORS

In the Bellevue cases (I refer now to the postmortem cases) bronchopneumonia was the commonest etiological factor, causing 44 of the 208 cases, about twenty-one per cent. Lobar pneumonia came next, then followed general sepsis, and acute infective endocarditis, in the order of frequency. Many conditions, then, are found associated, such as aortic aneurysm, cancer of the esophagus, and epithelioma of the tongue. Operations for hernia, mastoiditis, bone necrosis and extraction of teeth also were causes of lung abscess. None was recorded as due to a foreign body. In the past five years tonsillectomy was the cause of lung abscess in eleven patients, five of whom died.

PATHOLOGY

When one considers the pathological picture of bronchopneumonia, it is readily understood why it is such a frequent cause of abscess. Bronchopneumonia *is* an abscess, minus the death and liquefaction of the tissue. There is a dense infiltration of the bronchial walls and air cells. Their destruction results in the formation of an abscess in place of the pneumonic focus. In croupous pneumonia, the walls of the air vesicles are more or less intact. However, when destruction does occur, an abscess results. In the embolic type, as in infective endocarditis, there is a hemorrhagic zone with a gray liquefying centre. Surrounding this zone on all sides is a barrier of inflammatory tissue, and necrosis occurs frequently in this barrier zone. The liquefied centre gradually becomes larger and finally bursts into a bronchus, discharging its contents. In favorable cases the necrotic tissue separates, fibrosis occurs, resulting in an interstitial pneumonitis, with, in many instances, obliteration of the cavity.

In the cases of lung abscess following tonsillectomy, the manner of lung infection is a matter of some doubt and much dispute. Infection by inhalation is commonly declared to be responsible; others maintain that it is embolic, and occasional reference is made to the lymphatic route. The inhalationists, prominent among whom, strange to say, are the anesthetists, believe that faulty anesthesia plays a prominent part. Motor driven apparatus, improper suctioning of blood from the throat during operation, operating in the erect position, etc., are variously condemned.

Too profound anesthesia abolishes the cough or bechic reflex of the larynx, thus removing the laryngeal sentinel, and blood or bacteria laden cheesy particles from the tonsil are drawn into the lung. The frequency of these abscesses in the lower lobes, particularly the right, the regions in which aspirated foreign bodies most frequently locate, is additional evidence to substantiate their view. In rebuttal it is pointed out that it is very difficult, experimentally, to produce lung infection by insufflation methods; that lung embolism is most frequent in the lower lobes, particularly the right; that in not a few cases lung abscess has occurred after operation with local anesthesia, and these plainly are not by inhalation; that since tonsillectomy is followed by embolic abscess in the brain, why not in the lung?

It was referred to previously that lung abscess following tonsillectomy was first reported in 1912. It cannot be that these abscesses did occur before 1912 but were unrecognized. That seems impossible. Possibly they did occur but their causal relation to tonsillectomy was not apprehended, and that seems improbable. During the past ten years, the giving of anesthesia has become a specialty and marked improvement in its administration has resulted. Suction apparatus for the removal of blood and particles from the throat is constantly used. Formerly it was not. With all these safeguards it seems strange that lung abscess is increasing.

A point which seems to have been largely overlooked is that it was about 1912 that the operation

of beheading tonsils was succeeded by the one of enucleation. The essential difference pertinent to this discussion is that the enucleation operation lay open venous sinuses and lymphatic spaces in an infected area. The peritonsillar veins, forming a considerable plexus, lie in the wall of the tonsillar sinus, external to the tonsil and separated from it by the superior constrictor and the buccopharyngeal fascia. The constrictor muscle is delicate. Adhesions to the base of the tonsil are frequent, particularly after peritonsillar inflammation, and the enucleation operation may cause tearing of the fascia and injury of the venous plexus. It also brings an infected area into immediate contact with veins whose walls have been subjected to trauma, dangers not so imminent in the operation of tonsillotomy. The creation of infected thrombi follows, which later find lodgement, as infected emboli, in the lung.

Cutler and Hunt, of the Peter Bent Brigham Hospital, Boston, in a careful review of their postoperative pneumonia cases, conclude that practically all are embolic. From the evidence presented it seems that infection by the embolic route is as probable as by inhalation.

In a case studied recently in the Bellevue wards, the onset of symptoms was four weeks subsequent to the operation. This plainly is not embolic, nor does it seem probable that it was from aspirated material. It is more likely that it was a lymphatic infection, the course being from the superior cervical, to the inferior cervical, to the bronchial nodes, and thence to the hilus of the lung, and this abscess was situated around the hilus. It is of course recognized that the infection in its progress from the bronchial nodes to the hilus is traveling against the lymph stream, the normal flow being from the lung to the gland. Hilus tuberculosis associated with bronchial and cervical gland tuberculosis is quite generally accepted as having been from the glands to the hilus of the lung, and numerous other infections, elsewhere in the body, are explained by the transference of infection against the stream in either lymphatic or vascular system.

It seems probable, then, that lung abscess after tonsillectomy is frequently embolic, and also that it occurs by way of the lymphatics, and that these avenues of infection are made possible by the nature of the operation done in enucleation, viz., the laying open of venous and lymphatic spaces. That the inhalation of infected particles may cause lung abscess is of course not denied. To establish preventive measures, however, the responsible factors must be properly apportioned and to this end medical endeavor might be advantageously applied.

It may be well to speak here of a condition which clinically may closely resemble a lung abscess, but which pathologically is quite dissimilar. I refer to an interlobar empyema. A collection of pus, varying in amount from several ounces to a pint or more, may accumulate between the lobes as a sequel to pneumonia or as the result of embolism, causes which operate in producing a lung abscess. This pus may rupture into a bronchus and be discharged or break into the lateral plural space giving a lateral empyema. The situation, physical signs and x ray findings help to distinguish it. It is a more favorable condition than lung abscess, spontaneous cure frequently resulting. It is more amenable to surgery, also, than abscess.

DIAGNOSIS

First.—In pneumonia, failure to resolve promptly, an increase in temperature after it has subsided, the occurrence of late pain in the chest, and the sudden expectoration of a considerable quantity of foul smelling pus, call for the exclusion of lung abscess.

Second.—Pain in the chest following operation on the throat, or elsewhere, should call to mind the possibility of lung embolism and its consequences. The physical examination may reveal only dulness and a few moist râles, or the signs may be those of a pneumonic process. The x ray is an invaluable aid.

Third.—In some of these cases no antecedent causal factor is prominent, the onset being insidious and many of these are thought to be tuberculosis. The character of the sputum and the continued absence of tubercle bacilli serve to differentiate. The details of diagnosis are not within the scope of this paper.

In some, spontaneous cure results. Sloughing off of the necrotic tissue, fibrosis of the inflammatory barrier, referred to above, and in many, obliteration of the cavity occurring. Whittemore reports this favorable outcome in about six to ten per cent. of the cases. On the third medical division this was seen twice in sixty-one cases (3.2 per cent.). After what length of time may one cease to expect a spontaneous cure? Some say eight weeks, others six months. After a year's duration a spontaneous recovery is exceptional. The longer it is deferred, the less likely is it to occur.

Many patients die; mortality statistics give from forty to eighty per cent. of deaths. In the 169 cases studied clinically in Bellevue during the past five years, there were sixty-seven deaths, about forty per cent. The remainder were discharged mostly as unimproved. It will be of interest to note that in one of the fatal cases the lung abscess had existed for eleven years, in another for ten, and in several for five years. When a lung abscess does not terminate fatally, or in spontaneous cure, there ensues a condition of invalidism to which death itself seems preferable.

TREATMENT

Many therapeutic measures in vogue today are but imitations of nature's methods or designed to aid and supplement her reparative processes. An examination of the pathological changes during spontaneous cure may give us a hint for our therapeutic procedure. As stated above, there exists in these cases a barrier ring of exudate with necrotic margins lining the abscess cavity. Separation of the slough, followed by fibrosis, is the curative process. This necrotic rim is continually bathed in pus, containing liquefying ferments (from the bacteria and pus cells) which ferments attack the surrounding barrier making it more vulnerable and liable to death, thus promoting the extension of the necrotic area. Freeing the region from pus and keeping it free are the indications then to limit the amount of necrosis. Nature provides an exit by rupturing into a bronchus, and her expelling force is cough. Fibrosis is promoted by securing rest for the inflamed area. Air entering the cavity with each inspiration keeps this region in almost constant motion. The respiratory act as a

whole adds to the movement, and cough, nature's method of expelling pus, but exaggerates it. A lung abscess places nature's reparative processes in a serious dilemma. To secure freedom from pus, cough is necessary; to obtain fibrosis, rest. It is small wonder that failure is frequent.

From what has been said it is readily apparent that the indications are to free and keep free of pus the abscess area, to collapse the cavity and prevent air currents from distending its walls, and to limit as much as possible the respiratory excursion.

A priori, at least, artificial pneumothorax meets these requirements. The existence of pleural adhesions of any marked degree of density will preclude the possibility of collapsing the lung and obliterating the cavity. To be effectual, the compression must be done before the adhesions have become firm. Tewksbury, one of the first to recommend this, reports eighty per cent. of recoveries in cases compressed within six weeks of the onset. Rich, of Detroit, reports similar results. Clendenning and others advocate its use. If the abscess does not communicate with a bronchus, compression seems inadvisable. If the abscess is situated close to the periphery of the lung, only a narrow strip of tissue intervening, compression may cause a rupture into the pleural space, and is probably inadvisable. An abscess around the hilus, most inaccessible to the surgeon, seems the one for which compression is best suited. Unless curing spontaneously within three to four weeks, compression should be attempted, and if sufficient collapse is secured, must be persevered in for a considerable period. If there is failure in obtaining a cure the lung should be allowed to reexpand, when the pleural surfaces will become adherent, obliterating the pleural space, thus admirably preparing the site for what seems the next rational proceeding, viz., rib resection and the formation of a lung fistula. In this method drainage is obtained and rest for the lung secured, and the requirements for healing, as set forth above, have been met.

Placing the patient head downwards, so that the pus may gravitate from the abscess region, is advocated by some. When it is remembered that a patient can maintain this posture for a very few minutes, it is difficult to believe that adequate drainage can thus be secured. While, in our experience, symptoms may be ameliorated, it was not in any sense curative.

The bronchoscope has been warmly heralded both as a diagnostic and a therapeutic measure. If the abscess has not opened into a bronchus, the bronchoscope is of little value. If rupture into a bronchus has occurred, the bronchoscope as a diagnostic aid is superfluous. The x ray is more informative, and without risk.

It is to be remembered that a lung abscess is not only a collection of pus, but also very frequently a collection of pus with surrounding necrotic lung. The occasional removal of pus through bronchoscopic washings can have but little effect on this necrotic tissue. Cure is achieved when this necrotic sequestrum separates, and a lung abscess curing under bronchoscopic washings, would have cured spontaneously. Some of our cases had as many as fifteen to eighteen washings, with an aggravation of their symptoms. In the case of a foreign body abscess, the bronchoscope is of decided value both diagnostically and therapeutically.

Finally, there is lobectomy. At present this field is properly restricted to a few daring pioneers. For the majority it is inadvisable.

CONCLUSIONS

1. Lung abscess is of more frequent occurrence than is commonly held or stated.
2. Its clinical recognition is not always easy and the condition is often overlooked.
3. Spontaneous cure occurs in a small percentage of cases.
4. Lung abscess has a high mortality rate, forty to eighty per cent, and when not resulting fatally, there frequently ensues a pitiable state of invalidism.
5. Lung compression, if done early, holds some promise; if done late, very little.
6. Tonsillectomy by opening up venous sinuses in an infected area provides the opportunity for embolic invesion of the lung.
7. Finally, a condition so frequent and so serious is deserving of intensive study both for its prevention and its cure.

Urobilinuria

E. M. WATSON, M.D.
Sheffield, England

Urobilinuria is a term which expresses that an abnormal amount of urobilin is being excreted in the urine. Its significance is by no means definitely understood, although considerable research has been done and various theories propounded in an attempt to elucidate the clinical and biochemical relationships of urobilin and its precursor urobilinogen.

Urobilin is one of the better known of the urinary pigments, although normally it contributes but little toward the actual pigmentation of the urine. It was described first in 1868 by Jaffè (1). Several explanations have been suggested regarding the mechanism of formation of urobilin but probably the most commonly accepted one has been the socalled enterohepatic theory. From the iron and certain other elements of the food is built up hemoglobin. In the liver the hemoglobin is broken down again, undergoing dissociation into its protein and chromogenic constituents. The latter loses its iron and is converted into the bile pigment bilirubin. In the intestine, the bilirubin is reduced to urobilinogen, presumably as the result of bacterial activities. A great

part of the urobilinogen leaves the intestine with the stools, being called stercobilin; while a small part is absorbed into the blood stream and escapes by way of the kidneys.

This is the explanation which is given by most textbooks of physiology, but recent work would remind us that the history of urobilin is not so simple as that just described. Indeed, a review of the literature on the subject leads one into a confusion of conflicting opinion from which it is difficult to emerge with a satisfactory working hypothesis, having regard for all the evidence put forward. Addis (2) believes that after absorption, the urobilinogen is converted into a form which has not yet been identified, the socalled urobilincomplex. This urobilin complex is practically all taken up by the liver where part of it is built up again into hemoglobin. A part gets past the liver into the general circulation and is excreted by the kidneys as urobilinogen. Some may also be reexcreted into the intestine along with the bile.

A LIVER PRODUCT

Wilbur and Addis (3) intimate that urobilin may be a product of the liver itself. Jones (4) also maintains an intrahepatic origin for urobilin. This claim is based on the examination of the duodenal contents following the liberation of hemoglobin into the general circulation. There is an increase in the excretion of bilirubin followed after a relatively short interval by an increase in urobilinogen values. This time interval is believed to be too short to allow of intestinal action upon the bilirubin and subsequent reabsorption of urobilinogen, since bacterial action is not marked in the upper part of the small intestine. Whipple (5) also attributes urobilinogenesis as a function of the liver and bile passages with its absorption at times into the blood stream and subsequent appearance in the urine. This investigator discredits any absorption of urobilinogen from the intestine.

Even though differences of opinion do exist as to the exact site of origin of urobilin, this much is certain that a close relationship does exist between the blood pigment, the bile pigment and the urinary pigment, urobilin.

Bauman (6) has pointed out this relationship by a comparison of their formulas and it is observed that the greatest degrees of urobilinuria occur in those conditions associated with excessive haemolysis, either experimental or clinical.

MECHANISM OF BILE FORMATION

The mechanism of bile formation is yet but vaguely understood. Recent studies have proved that this substance may be formed without the intervention of the liver at all, following the introduction of hemoglobin into the circulation (7, 8, 9). The possibility suggests itself that urobilin may on occasion have an origin apart from either the liver or intestine. As a matter of fact urobilinuria has been observed to follow intra cranial hemorrhages (10), retrouterine hematocele and extrauterine pregnancy (11).

Urobilin occurs in small quantities in the urine of normal persons. In the blood, there is very little evidence of urobilin or urobilinogen having been identified as such. Bauman (6) was unable to demonstrate it in the serum of patients even when they were excreting considerable quantities in the urine. Herzfeld (12) found traces of urobilin in only seven out of four hundred specimens of blood serum examined by the zinc acetate fluorescence technique.

Several methods have been described for the quantitative estimation of urobilin in the urine (3, 13) all depending upon some characteristic property possessed by this pigment substance. A convenient but perhaps not the most accurate method quantitatively, is that devised by Marcussen and Hansen (14). It is an application of the Schlesinger reaction which depends upon the fact that urobilin, in the presence of certain zinc salts produces a green fluorescence. The urine is put through a series of dilutions and the greatest dilution which shows fluorescence is noted. Normally fluorescence is not obtained in a dilution greater than one in twenty but in certain pathological conditions it may be obtained with quite high dilutions even up to one in two hundred. A similar technic has been used by Adler (15) and Herzfeld (12).

ELIMINATION OF UROBILIN

The greatest elimination of urobilin occurs in those conditions associated with an excessive blood destruction. The hemolytic anemias give the highest values. Increased urobilin output has been reported in pernicious anemia and malaria (16, 17). Urobilinuria has been observed in various hepatopathies such as cirrhosis of the liver and severe hepatitis also as a result of the liver degenerations accompanying the toxic infections. This is explainable on the ground of the liver playing a rôle in the production of urobilin.

The diagnostic value of urobilin determinations in the urine is apparent from the viewpoint of differentiation between obstructive and hemolytic jaundice. In the absence of increased blood destruction, a urobilinuria may serve as an indication of diminished functional capacity of the liver.

Malignant Neoplasms: Colloidal and Electrical Phenomena Observed and Their Experimental and Clinical Aspects*

DONALD C. A. BUTTS,
Philadelphia.

In the whole realm of science there is without doubt no subject more studied, theorized about, and investigated than the cancer problem. When we look back through the ages and find that this disease was recognized and treated as early as 1500 B. C., and since that time has been the source of extensive theoretical and experimental study, the complexity of our subject is indeed obvious. So many theories and explanations as to the etiology and progress of the disease have been advanced, argued pro and con, that the investigator of the present day is in a quandary as to the most logical field of pursuit. It is likewise clear—that, despite the findings of former workers, we must explore fields yet untrodden, if we hope to advance our knowledge of the cause and treatment of cancer. In view of the countless number of elaborate dissertations on the pathology and physiological chemistry as related to our problem, it is apparent that the answer to the question, What is the cause of cancer? lies beyond the scope of these independent fields of science.

Much credit is due pathologists, chemists, and bacteriologists who have advanced or disproved various theories, and who, through their untiring efforts, have made possible a fairly accurate diagnosis of the disease, but unfortunately only after the disease has run its course and advanced from the state of benignancy to one of malignancy. Likewise, laudable credit is due the clinician or surgeon to whose attention and skill such sufferers are first subjected; who fight along under the greatest difficulties, knowing that in his hands lies the future of this individual, without any adequate treatment to offer but the knife and radiation. If recognized in its socalled premalignant stage, the fight is most probably won, but how many physicians are gifted with such good fortune?

I shall not at this time even mention the various pathological pictures demonstrated in the numerous forms of the disease, nor shall I attempt to review the theories presented in the past, with which you are all more or less acquainted, but for convenience and thorough understanding of the experiments undertaken, I shall review briefly the theory of cell ionization as brought forth by me at an earlier date (1).

Briefly, by the term cell ionization I mean the distribution of positive and negative charges or ions within the individual cell body. When proper balance and distribution of these ions are present, normal metabolism, functioning and life cycle of the cells result, but any disturbance in this balance manifests itself in the various pathological conditions within the body.

Theoretically, and I believe I can now also say experimentally, it seems that an increase in positive ions or a decrease in negative ions within the cell body results in stimulated reproduction, while on the other hand, a decrease in positive ions or an increase in negative ions, I believe to result in an opposite action, i. e., inhibited propagation, resulting eventually in vital passivity, depending upon the intensity and period of action of the exerting negative charges.

Therefore, it can be seen from the foregoing hypothesis, that the cells which comprise our entire bodies are composed of positively and negatively charged portions continually in active motion, which interchange; and their combinations and recombinations produce the various chemical, thermal and electrical changes necessary to carry on the organism, and if this molecular motion is stabilized simultaneously throughout the cell death will result. Without doubt you have already wondered in what way this normal electrochemical distribution of the ions within the cell may be disturbed, and how we can directly associate such a disturbance with the etiology of cancer.

Some time ago, while making a thorough study of the cancer incidence among the lower animals, I was much impressed with the absence of cases reported involving the udder of the cow. At that time, after an exhaustive negative search for a single case, I issued a preliminary report on the immunity of the bovine udder to carcinoma (2). I was equally impressed with the fact that this organ was quite susceptible to tuberculosis, which state of affairs is exactly contrary to that of the human breast. Results of experiments conducted by myself, following the publication of this report, are extremely interesting. Through the elimination of possible factors responsible for this apparent localized immunity of an organ to cancer, it became quite obvious that it was one of an acquired resistance, because if traumatism, lactation and other factors are considered in the etiology of cancer, surely this organ would offer a most fertile field for the development of this disease.

Alexander Garcia, working on a vitamine of resistance in the treatment of tuberculosis, was able to wall off the tuberculous process by the application of such treatment and a section taken from this newly formed defensive tissue so simulated a sarcoma that the differentiation was practically impossible. In this experiment the animals suffering from tuberculosis might be considered cured of this disease by a condition closely resembling cancer but limited and governed in its process. This same vitamine injected into animals bearing the Flexner rat carcinoma, hastened to a marked degree the destructive process of this tumor over the control animals not subjected to treatment.

Now we all know that one individual is rarely the host of these two maladies, tuberculosis and

*Read before the Alumnæ Association of the Woman's Medical College of Pennsylvania, June 14, 1923. For the technic of tumor transplantation, see author's report, Technic for the Removal and Transplantation of Rat and Mouse Tumors, *Journal of Laboratory and Clinical Medicine*. Vol. VIII, No. 8, May, 1923.

cancer, and this, together with the above mentioned conditions may be explained, I think, as follows:

As stated earlier in this paper, I believe the cell to be composed of positively and negatively charged portions or ions in definite ratio, depending upon the organ or part involved, and such portions or ions to be in active motion, thereby allowing the cells to function and to complete their life cycles. The balance of such ions is by no means constant, which ratio establishes the index of resistance of an organ or part to stimulated propagation and the formation of cancer. Now if this theory, which experiments seem to prove true, bears any connection to our problem, and the exciting factor to carcinoma and other malignant new growths is of a positive nature, then any part exposed to traumatism and constant irritation, generation after generation, acquires a balance of its ions, with the ratio of the positive and negative ions much different than one little exposed to traumatism and positive stimulation and are therefore not as susceptible to the action of a positive stimulus. Here their index of resistance has been raised to offset much stimulations.

Upon this reasoning it is easily seen how the udder of the cow, through natural environment, due to its position, which is one continually exposed to friction between the hind limbs; its frequent periods of lactation, which have appropriately termed it a "milk machine," have established a resistance unaffected by positive stimulation such as would produce cancer of mammary origin in other species.

Regarding the action of the previously referred to vitamine of resistance, it is quite apparent in my estimation, that it exerts an electropositive action upon the cells with subsequent stimulated cell propagation. I shall state at this point that this theory may oppose in some respects the prevailing ideas held regarding the action of x ray and radium therapy in the treatment of malignant neoplasms, but upon careful consideration and study of results obtained in the past, and applied to the various theories and treatment of earlier investigators, I feel that the explanation herewith presented demonstrates an alterative rather than a destructive process brought about within the cell.

We are all familiar with the fact that histologically an individual cancer cell cannot be differentiated from a normal cell, and that the predominant property of such malignant cells is that of propagation and subsequent infiltration. Likewise, living matter is differentiated from that which is lifeless by the property of the former to reproduce, a property which is not possessed by the latter. Applying these known facts of oncology and biology to our problem it is reasonable to believe that whatever this factor is which endows the formerly normal cells with excessive proliferative powers, it must be one of stimulation rather than destructive; *surely dead cells cannot reproduce.*

We also know that all impulses, whether voluntary or involuntary, are the result of electrical conductivity, and with this knowledge it is reasonable to believe that whatever governs the metabolism of the individual cells must also be of an electrical nature, and that all properties of the cells, including that of division, do not occur in the regular, well defined schemes without direct stimulus and control.

As stated before, it is my contention that carcinoma is due to the effect of an excess of positive charges or ions within the cell nucleus, which overbalance of positive charges, whether due to the direct exposure to the positive rays from the röntgen tube or the alpha particles of radium (both of which are at the present time carefully screened off); or to an altered neuroelectrical cellular control, caused by chronic irritation or traumatism, will stimulate the cell to the various chemical and pathological characteristics and processes demonstrated during the development and course of cancer.

If this explanation is true, we could expect to find in metastatic growths the material for our investigation, because here we have the cells from the primary site actually giving rise to new growth, which cells must be endowed with the property and power which gave rise to the original tumor.

Therefore, the first step taken in support of this suggestion was to determine, if possible, whether or not the cells comprising a carcinoma were of different electrical reactivity from those of normal tissue. So complex is such an investigation that I shall limit the following brief résumé of my experiments to this particular subject, although numerous collateral points are being investigated.

The first step in such an investigation was how to determine this overbalance of positive charges or ions within the cells comprising a carcinoma, and this constituted the first few weeks of our research.

Through the courtesy and generosity of Dr. William H. Woglom, assistant director of the Crocker Laboratory of New York City, I was able to establish the Flexner-Jobling rat adenocarcinoma in our laboratory, which tumor was used for all of the following experiments and verified by pathological examination. On the night of January 17th, while working alone in the laboratory I made a rational and most fortunate experiment, using a type H. S., reflecting, Leeds and Northrup galvanometer to determine the polarity of normal and tumor cells.

Taking two female rats of the same litter, of known age and strain, one which I knew to be free from any pathological condition and the other bearing the Flexner-Jobling adenocarcinoma, I connected these much in the same manner as one would connect two batteries by means of a twenty gauge platinum wire. One end I introduced subcutaneously into the normal rat, the other end into the healthy border of the tumor, free from necrotic matter. Then taking two pieces of fine copper wire, to which were fastened a platinum electrode, I inserted each electrode into a different portion of each animal. In the case of the tumor animal, the electrode was placed into the opposite border of the tumor from the wire connecting the two animals. The other end of the copper wires were fastened to the binding posts of the galvanometer in such a manner that the wire from the tumor animal was fastened to the right hand binding post of the galvanometer, and that from the normal rat to the left hand binding post. By pressing a single contact key which had been inserted into the circuit I received a deflection of the galvanometer mirror to the right over a very readable distance on the galvanometer scale. If my contention was correct, the animal

bearing the tumor should act as the positive pole and the normal rat as the negative. To determine the correctness of this polarity, I connected the electrodes in exactly the same order to the known poles of a standard cell, which, upon completing the circuit, deflected the galvanometer mirror in the same direction as did the animals, but to a much more marked degree. By reversing the electrodes in the animals or at the binding posts of the galvanometer or by means of reversing switches, deflection in the opposite direction was brought about. This experiment has been repeated some one hundred and fifty times, and with but one exception, where explicable conditions interfered, has always displayed the same results, even though the animals are separated by a distance of ten feet.

Some of the experiments described above were witnessed by Mr. Otto Borman, a well known radio authority, who suggested that further investigation as to the nature of the results obtained might be carried out with the use of a vacuum tube such as that used in radio reception. He conceived an arrangement of apparatus whereby the characteristics of this tube might be studied, and the apparatus supplied to the experiments mentioned above.

The action of this tube is such that when the filament is lighted and a voltage impressed upon the plate an electron flow takes place between the filament and the plate. Inserted between the filament and the plate is a wire grid. When the grid is given a positive or negative charge a change takes place in the electron flow. The electron flow, as shown by the deflection of the galvanometer mirror, is constant when the grid does not contain an electric charge and deflection of the mirror varies with the kind of charge and also with its intensity. As sufficient time has not elapsed since this extensive experiment was started accumulated data as to my results is not yet available.

The possibility of the interference of thermal changes and the degree of anesthesia has been eliminated by experiment. Therefore, due to the great number of times this experiment has been repeated, and the uniformity of the results obtained, I feel that I am justified in saying that the tumor bearing animals have a higher or greater potential than the normal rats, which change in potential is due to an excess of positive charges or ions within the cells comprising the neoplasm.

Realizing the difficulties involved in the solution and explanation of a subject so complex as the one with which we are dealing, I have merely attempted to offer the most logical explanation as brought to my mind by the results I have obtained in my research, and reserve the right to alter or modify such explanations as further experimentation and research deem necessary.

The determination of polarity being fairly well established, the next logical procedure was to repeat such experiments substituting the anionic and the cathonic colloids for the normal and tumor rats, respectively. I shall not repeat the procedure of the experiments, as I feel that it is sufficient to state that, using a strong electropositive colloid of iron and an electronegative colloidal sulphur, the deflections were the same as with the normal and tumor animals. Such experiments were subjected to the same close observation as were my animal experiments.

The most striking feature observed was the fact that when these oppositely charged colloidal sols were placed in separate, alkali free glass containers, and a wire from each independently connected with the binding posts of the galvanometer, they produced no deflection of the galvanometer mirror until a wire connecting the two was inserted into the sols. Placing the two electrodes into the same sol we found might deflect the mirror in either direction; however, in the great majority of cases, an anionic colloid caused deflection to the left and a cathonic colloid to the right. This last mentioned phenomenon can only be accounted for by the fact that colloids, whether anionic or cathonic, are composed of positive and negative charges or ions, the predominating ones determining the classification of the colloid, and under these conditions the almost constant results obtained with single colloids might be explained.

From two opposite colloids, connected in the same manner as the animals, and the circuit closed, I received a maximum deflection, which, in course of time reached the zero point on the galvanometer scale. Dark field examination of the colloidal sols before the experiment displayed active Brownian movement of the colloidal particles, but when examined after the galvanometer reading had reached the zero point, practically all Brownian movement had ceased and the particles showed marked grouping of agglutination.

Having observed the electrical behavior of normal and tumor rats, anionic and cathonic colloids, the next step was to determine the effects of these colloids upon tumors. Animals connected as previously mentioned and displaying the regular electrical action, i. e., causing deflection of the galvanometer mirror to the right, were treated as follows: Usually 0.5 c.c. of colloidal sulphur sol (negatively charged passing to the positive pole) was injected subcutaneously or directly into the tumor. The animal was allowed to rest for several hours or over night, thus allowing time for absorption of the colloid to take place. After this time had elapsed the same two animals were connected as before and upon completing the circuit deflected the galvanometer mirror in the opposite field. This experiment apparently showed that the cells (tumor cells) previously with a greater potential now possessed a lesser one than the normal animal, i. e., that the positive charges or ions within the normal animal were in excess of those of the treated animal. These animals, allowed to go for several days without treatment, again caused the characteristic deflection as before treatment but not to so great an extent.

I might go on mentioning the many experiments which I am conducting through the kindness of the Philadelphia College of Pharmacy and Science, in their laboratories, also those necessary to place such an extensive and involved work upon an indisputable scientific foundation, but as I wish to say just a word regarding the clinical investigation in support of this theory, I will limit such experimental study to the above mentioned research.

Regarding the clinical use of the anionic colloids, particularly colloidal sulphur, due to its nontoxic properties and the fact that it is the most

powerful electronegative colloid now at our disposal, all that I feel justified in saying is, that a number of cases under such treatment have shown a marked improvement to date. Whether or not this improvement proves to be a permanent one requires a much extended period of time to determine.

Although I could cite a great many interesting cases, and conditions manifested in cases under treatment, I feel that this information could best be obtained from those who have so kindly cooperated in this investigation by their clinical experience and knowledge.

CONCLUSION

In concluding, I wish to state that my experiments all tend to prove that the tumor cells possess a higher potential probably due to the existence of an excess of positive particles, charges or ions, which experimental work is apparently clinically supported by the marked improvement in many cases treated with the electronegative colloids, which I believe bring about a neutralization of such excessive positive ions and readjust the tumor cells to normal metabolism and habit chemistry. Such a process is one of rehabilitation rather than destruction.

Although our results obtained by the application and administration of the anionic colloids in the treatment of malignant neoplasms are very encouraging and the end to which we may look for a beneficial and scientific treatment of such growths, I feel that our present preparations, although scientifically made to the best of our present day knowledge of colloidal chemistry, are in need of extensive research and improvement.

I wish to take this opportunity to express my hearty thanks and appreciation to all who have so ably assisted in this research and most sincerely hope that this work may mean one more step forward in combating one of the gravest maladies known to mankind, cancer.

Granuloma Inguinale*

H. L. HORWITZ, B.S., M.D.,
Chicago, Ill.

INTRODUCTION

Considerable discussion had been evoked of late regarding the subject of granuloma inguinale. Not recognized in the past as a definite clinical entity, this ulcerating cicatrizing, serpiginous lesion of the pudenda and mucous membrane has been a confusing condition to clinical men; and up to fairly recent times has been a stumbling block in the pathway of successful therapy. Careful scientific work under ideal conditions in various portions of the world, particularly in the tropics, has gradually established the fact that these socalled tropical ulcers described under a great variety of names have a definite entity, a definite clinical resemblance, and that they can be fairly successfully combated. Case reports of this hitherto considered rare lesion have been accumulating in the literature and there is a striking uniformity in many of the clinical descriptions of this disease process.

We are indebted to Conyers and Daniels (1) for the establishment of this condition as a clinical entity, removing it from that vague and meaningless term, tropical ulcer. Since then a great number of men have reported this condition in the literature, described it in scientific detail, and presented a new mode of successful treatment. Among the men may be mentioned Campbell (2), Goodman (3), Lynch (4), and Cumming (5). With this advance in knowledge of the condition proper, there has developed a marked advance in the number of reported cases and particularly a marked advance in our knowledge of eradicating it. The horizon no longer reveals that hopeless, indifferent outlook to these chronic, indolent, progressive and not uncommon lesions.

*From Louisville City Hospital.

ETIOLOGY

The disease is common in the period of sexual maturity—children rarely acquire the disease nor individuals above the age of forty-five. Both males and females are effected; race plays no essential causative part, although a few believe that the negro race has a greater susceptibility.

The immediate exciting factor is not definitely known—there is a theory advanced by Wise (6) as to the responsible agent being of a spirochetal origin. Donovan (7) suggested the socalled Donovan bodies or inclusions as playing the causative rôle. The views of Donovan have apparently been given rather wide acceptance; he describes small rod or coccuslike bodies usually about four microns by one micron in size, lying singly or in groups in the mononuclear cells, obtained by scraping the ulcerative areas, the organisms taking the gram stain. Few investigators have confirmed these findings, but these socalled inclusion bodies have been noted at times to be completely absent from typical lesions.

HISTOPATHOLOGY

The histopathology is essentially a chronic, low grade inflammatory process with a concomitant exuberance of granulating tissue. There is a round cell infiltration of the corium and of the papillæ, and

also to variable extent down to the subcutaneous tissue. The hypertrophied papillæ so commonly seen is due to the cellular infiltration.

The diagnosis of this lesion up to a comparatively recent time was confused with syphilis, yaws, tuberculosis and epithelioma; probably because of our habit of credulity. The lesion as it appears clinically is distinctive by its chronicity and the light red, shiny mass of granulating tissue that bleeds easily and exudes a thin, light, sanguineous fluid with almost a pathognomonic fetid odor. The margins of the lesions are raised and the centre sunken. With this more or less extensive lesion there is no enlargement of the draining lymph nodes and the general well being of the patient unaltered.

This condition is differentiated from a primary by the history of chronicity and the absence of lymphatic involvement; from condylomata lata by the presence of granulating tissue. The Wassermann is of some help. The distribution and the lack of the multiplicity of the lesions distinguishes it from yaws. The absence of Koch's bacillus rules out tuberculosis of the skin. The microscopic section rules out neoplasms.

The treatment of granuloma inguinale at present is specific, consisting of intravenous injections of one per cent tartar emetic (Campbell). Some workers, in conjunction with intravenous therapy, have administered tartar emetic by other routes such as intramuscularly (Cumming) and orally (Goodman).

The mode of treatment in the case herein reported was that of intravenous medication. Five grams of antimony potassium tartrate was dissolved in distilled water. This solution was then filtered through a Berkefeld filter and acidulated with five drops of chemically pure hydrochloric acid. The solution was then ready for intravenous use which was accomplished with a ten c. c. syringe. The first injection given was two c. c. of the one per cent solution of tartar emetic diluted with eight c. c. distilled water. Every other day the solution was increased by one c. c. and the distilled water decreased by one c. c. and thus this was continued until twelve c. c. of one per cent solution was given with no reaction nor any discomfort to the patient. However, the patient felt an itching sensation in the ulcerative area. In passing, I might mention that on several occasions by some fallacy in technic a small amount of the solution escaped into the subcutaneous tissue which produced a burning sensation almost immediately and later produced an indurated area at the site, but with no untoward effects.

Case.—Patient, C. G., male, white, adult, about forty-nine years of age, from Elizabeth, Ky., entered Louisville City Hospital, August 24, 1922, with a provisional diagnosis of anal fistula and with the following complaints: Ulceration on right cheek of buttocks extending down along the folds of buttocks and up to the base of the scrotum and around the inner surface of both thighs up over the pubis (three inches) and over both inguinal regions. This according to patient's history began as a boil between folds of the buttocks about four years ago. The boil broke down and began spreading progressively.

At time of entrance to the City Hospital the lesion appeared to be superficial with a raised border of an exuberance of granulation tissue which was hard and made up of numerous reddish brown elevations the size of a pea. The centre of the lesion was smooth and reddish blue in color with a yellowish, purulent, fetid discharge bathing it. Patient asserted that it would itch during the night only. Areas, apparently healed, were present having a tissue paper appearance, pinkish in color, and a brownish, nonelevated border.

The family history was negative. The patient had had typhoid fever when ten years of age, whooping cough and measles during childhood G. C. and chancre denied. He smoked and drank moderately. He had no vertigo or headache, heard and saw well, had palpitation of heart at times, but no dyspnea and no cough. The bowels were usually constipated; no dysuria or nocturia.

Physical examination revealed extensive ulceration. Pupils were equal and regular and reacted to light and accommodation. Teeth were in poor condition; no adenopathy of neck; heart and lungs revealed no pathology; no tenderness nor involuntary rigidity of abdomen; no palpable inguinal adenopathy.

Laboratory findings: Urine: specific gravity, 1.020; negative for albumin, sugar and casts. Blood count, white blood corpuscles, 6,800; polymorphonuclears, 45 per cent; lymphocytes, 46 per cent.; transitionals 8 per cent. eosinophiles, 1 per cent. Wassermann was negative. Smear revealed pus cells, gram positive cocci, pairs and singly; no evidence of Koch's bacillus. Microscopic section showed acute and chronic inflammation, no evidence of tumor.

CONCLUSION

The treatment previously described was continued for a period of seven months and definite clinical improvement was observed. In many places the ulceration healed over entirely. In other places the lesion became superficial and numerous white, raised areas of epithelization appeared; the fetid odor and discharge became markedly lessened. The progress was extremely satisfactory to the patient. In the latter part of March, 1923, the patient decided to leave the hospital, feeling that his condition had improved to that extent.

Appreciation is shown to Dr. William J. Young and Dr. John Walker Moore for verification and advice.

Practical Therapeutics

CALCIUM INHALATIONS IN THE TREATMENT OF PULMONARY TUBERCULOSIS*

F. Tweddell, M.D.

Great Neck, N. Y.

It seems strange that no practical use has been made of a condition first noticed by a French physician, Renon, in 1906, and a little later, in 1909, by a Spanish physician, Fisac, viz., that all men employed in lime or plaster of Paris works were immune to tuberculosis. Thousands of men are employed in this industry, year in and year out, and as yet no cases of tuberculosis have been reported among them. Is it not then reasonable to suppose that this immunity is brought about by the inhalations of the dust of lime and plaster of Paris in these factories? It is inconceivable that it could be due to any other cause, for the calcium dust is the common factor in all the localities where this immunity has been observed. It is but a step further to conclude that calcium is a specific in tuberculosis, and as we have lamentably few specifics in medicine, it should be our aim to add to them.

I pointed out in a former paper (1), that pulmonary tuberculosis, bearing in mind the anatomy of the lungs, can be treated only in two ways, namely, by inhalations or by intravenous injections, whereby the medication will reach every part of the lungs. By inhalations the fine particles of calcium oxide or calcium sulphate penetrate to the remotest parts and there set up an alkaline antiseptic reaction with the moist tissues, which tends to overcome the acidosis nearly always present. The constant associated deficiency of calcium is thus also corrected. It would be difficult to imagine a more ideal method of administering treatment.

Every conceivable remedy has been tried in pulmonary tuberculosis without any logical reason. Here, however, we know that all men who inhale lime or gypsum are free from tuberculosis, and it is only fair to the many sufferers from this disease that we should give it a trial. I apologize for the small number of cases I am about to report, but I can not get facilities for trying out this treatment on a large scale at some hospital. I am sure I have tried.

CASE REPORTS

Case I.—In July, 1919, the patient, a woman, came to me. She had been sick for about five years and had small cavities in both apices, as well as râles in every part of the chest. I treated her with inhalations of sulphur dioxide and she improved up to a certain point, i. e., her temperature stayed normal and all râles had disappeared, but the pulse rarely went below 100, her appetite was waning, she was losing weight, although she had put on flesh when she began treatment, and she still felt short of breath after exertion. I realized then that the action of sulphur dioxide was purely antiseptic, and its reaction decidedly acid. Some other remedy was needed to overcome the acidosis and replace the loss of calcium. Nothing could be better suited for this purpose than inhalations of calcium oxide or calcium sulphate. A few months previously I had investigated conditions in lime and gypsum plants in the northeastern part of the United States, as well as most parts of Canada, and learned that not a single case of tuberculosis had been observed among the men employed in these plants. Furthermore, some of the managers noticed that men suffering from coughs and colds when first given employment soon recovered. It is quite possible that a certain percentage of these men were tuberculous. For these reasons I thought it would be advisable to give inhalations of calcium to my patient. I therefore obtained some chemically pure calcium oxide, ground it to powder in a mortar and put it in a powder blower. I asked the patient to use this powder blower for a few minutes three or four times an hour. At the end of twenty-four hours she informed me it was very irritating, that it burnt her mouth and throat. I requested her to discontinue these inhalations and wondered why this treatment had failed. I did not discover the cause till three years later. The pure calcium oxide and the pure calcium sulphate are both very irritating to inhale, because they set up a violent reaction on coming in contact with the moist tissues. The commercial products do not cause any discomfort, because each molecular group has already absorbed two molecules of water from the air.

Case II.—On March 14, 1922, I was called to see a patient, a married woman, Mrs. A. D., of Great Neck, twenty-four years old. She had contracted pulmonary tuberculosis four years previously, when she weighed 130 pounds. She had been bedridden since the previous August, and then weighed 108 pounds. A specialist had seen her in October and told me that at that time she was a hopeless case and might live another three or four months. In appearance she was terribly emaciated, with sunken eyes and cheeks, prominent nose, cheek bones, jaws and ribs, flushed cheeks, very thin arms and legs, etc. During the previous few weeks her temperature had varied between 101° and 104°, the pulse between 120 and 140. There was loss of appetite, constant cough and great prostration. There was a large cavity in the left apex, noticed by everyone in the room, by the bubbling and gurgling sounds whenever the patient breathed. There were signs of a consolidation in the right second interspace near the sternum, and there were râles in every part of the chest, such as you find in all far advanced cases. Her diet consisted of a few glasses of milk, a little orange juice and some soup. During the next few days I gave her two intravenous injections of a calcium solution, that I have been using for the past six years, but she did not show signs of improvement. On March 20th I gave her a powder blower half filled with plaster of Paris and asked her to keep the nozzle about fifteen inches from her mouth and inhale the dust deeply into her lungs for a few

*Read before the Section of Medicine, New York Academy of Medicine, May 15, 1923.

seconds, and to repeat this four or five times an hour during her waking hours.

On April 4th, two weeks later, the râles had greatly diminished everywhere, especially in the lower part of the lungs, and the bubbling and moist râles were fewer. The signs of consolidation in the right interspace had disappeared, in the same manner as I had noted in other cases after inhalations of sulphur dioxide, which I reported over four years ago. Her appetite began to improve, and she was eating chops, steaks, and so forth, together with the usual vegetables. Her highest temperature for the day was 99.4° and her lowest pulse 104.

On April 11th, three weeks after treatment began, she was lifted out of bed and allowed to sit up in a chair. Temperature, highest, 98.6°; pulse, lowest, 100. No one in the room could now hear any moist or bubbling râles when the patient breathed. Using the stethoscope, I found a few moist and many dry râles in the cavity at the left apex. There were some areas in the chest where there were no râles at all, mostly in the lower part. On April 27th, temperature, highest, 98.6°; pulse, lowest, 98, very few râles anywhere; only a few dry rales in the cavity.

On May 8th, temperature, highest, 98.6°; pulse, lowest, 96. The patient now complained of a dry throat and I therefore advised sulphur dioxide inhalations. She took these inhalations mornings and evenings for five minutes. The sulphur dioxide counteracted the dryness and materially assisted in clearing the lungs of decayed tissue. I have reported the action of sulphur dioxide in a previous paper (2), and therefore cannot go into details here. However, during the first few days of its use the patient brought up many gray lumps. Later the color of the sputum changed to yellow and occasionally to white. She was now carried down to the garden at the back of the house where she sat most of the day, occasionally taking a short walk up and down the path. Once she went for an automobile ride for an hour.

On May 20th there were few dry râles in the cavity and few râles at the right apex. Temperature was normal and the lowest pulse was 92. On June 4th, at 4 a. m., she got out of bed suddenly to close a window, because a gust of wind had blown some things off a table. She reached the window and dropped dead, probably from acute dilatation of the heart. She had no hemorrhage. From the progress of this case I have no doubt that her condition would have become arrested. I had repeatedly warned her not to get out of bed unassisted and to avoid any muscular exertion.

Case III.—On October 23, 1922, I saw a married woman, Mrs. H. W., of Little Neck, twenty-two years old, who had lost weight and strength during the past six months, felt tired, had no appetite and did not sleep well. She had a slight cough and occasionally raised yellow sputum, which was not examined. The x ray, taken three months previously, showed peribronchial infiltration of both lungs as well as mottling and haziness of the left apex, suspicious but not positive of tuberculosis. There were no râles. Her temperature was normal but her pulse was 92. She was given a powder blower and instructed how to use it. Three weeks later she came back. She had not coughed for about ten days, had slept well, had a good appetite, had gained three and a half pounds and felt perfectly well. I have not seen her since.

There has always been a great objection to deep breathing in tuberculosis. I could never see any reason for this, for it is better to get good air into every part of the lungs than to leave part of them with stagnant air. The tubercle bacilli find a suitable breeding ground at the apex owing to the stagnant air, but seldom at the base, which is well aired. When you use sulphur dioxide or calcium sulphate inhalations, as I have, you will notice that signs of tuberculosis disappear first at the base, and much later at the apex, which demonstrates conclusively that the base of the lung is better aerated than the apex. Investigators have recently shown that deep breathing in tuberculosis is beneficial. Otabe (3) has demonstrated that deep breathing has a retarding influence on the tuberculosis process.

Leuchtenberger (4) describes the action of calcium as follows: "On the heart it resembles digitalis, it assists in the coagulation of the blood, it diminishes nervous and muscular irritability, it increases the phagocytic action of the leucocytes, it is also antiinflammatory and antiexudative." Decalcification exists in all diseases and conditions in which nutrition is at a low ebb. Lack of calcium means that metabolism is at fault, consequently, food is not being digested and assimilated as it should be, and accounts for loss of appetite in tuberculosis. Given a certain pathological condition of the lungs and having applied thereto a certain chemical reagent, the resultant chemical reaction should invariably be the same, with the exception of idiosyncrasy in a very small percentage of cases.

Bovine tuberculosis also appears to be due to deficiency of calcium. The Ohio Agricultural Experiment Station published reports (5) showing that *without exception* there was loss of calcium in every milch cow, varying from about two to eighteen grams a day. In a group of six cows, the average loss was over fourteen grams a day. It was shown that the cows for some unknown reason were all obliged to draw upon their skeletons in the production of milk. The fact that a milking cow loses calcium at the same time she receives a supply greatly in excess of the amount utilized, shows that the bones are more readily accessible for use in milk production than the calcium of the ration. And I might add that the administration of calcium by mouth to tuberculous patients is equally ineffectual, and like cows, human beings draw upon their bones for the supply of calcium. Milch cows often have disease of the bones as a result of this loss, and tuberculous patients often show decalcification, of the bones as proven by radiographic plates.

Coutière (6) more than a year ago used inhalations. The atmosphere was heated by electricity, saturated with lime and mixed with carbon dioxide in varying proportions. The inhaler was used for five minutes ten to twelve times a day. Signs of disease rapidly subsided, while the strength of the patients increased. Fluoroscopic signs of calcifi-

cation also became apparent. The same treatment was tried independently by another physician, who reported forty per cent. of apparent cures.

This treatment by calcium inhalations is so cheap, so simple and so harmless, and, in my opinion, so efficacious, that I hope no one who is interested will hesitate to give it a trial. As we know, the germs of tuberculosis obtain entrance into the body usually through the lungs, and it is surely not unreasonable to introduce the remedy, which will kill the germs or arrest their growth, through the same channel. The harmful action of destructive gases on the lungs has been widely demonstrated, and I am convinced that there is an equal opportuunity for successful experimentation in the use of inhalations which will have a beneficial effect when correctly used.

COMMENT

Since reading this paper, I tried the commercial lime for inhalations. It should not be used for this purpose, as it is irritating, causing severe coughing, whereas the commercial plaster of Paris does not irritate. I can give no reason for this.

An editorial appeared in the *Journal A. M. A.* on June 2, 1923, entitled: Calcium Therapy in Tuberculosis, which is incorrect and misleading. The first sentence reads: "The resistance to tuberculosis of those who work in lime dust is traditional." The writer then proceeds to give a long dissertation on the uselessness of administering calcium salts by mouth, and calcium chloride subcutaneously and intravenously. In this statement he is perfectly correct, but no mention is made of the fact that workers in lime or gypsum are immune to tuberculosis, because they inhale it—they do not eat it, although they must swallow some of the dust—neither do they have subcutaneous or intravenous injections. The article ends with the emphatic statement: "Certainly there appears to be no scientific basis for their continued utilization," i.e., of calcium compounds.

The plain fact still remains unchallenged, that workers in lime and gypsum do not suffer from tuberculosis—because they inhale calcium.

THE TREATMENT OF SKIN AND SURGICAL TUBERCULOSIS BY THE X RAYS AND QUARTZ MERCURY LAMP*

Samuel Feldman, M.D.

New York

Associate Attending Beth David Hospital; Adjunct Attending Bronx and Lebanon Hospitals; Chief of Clinic, Bronx, Lebanon and Beth David Hospital Dispensaries, New York.

These cases are presented, not because of their rarity, but because they serve as excellent examples of what can be done for a large group of cases usually so difficult to handle both surgically and medically. They tax the patience of both physician and patient to the limit. Those who have attempted to treat skin tuberculosis with ointments, curetting, and cauterization will testify to the fact that the results do not compensate for the effort on the part of the physician and the prolonged suffering of the patient.

Surgical treatment of tuberculous adenitis leaves unsightly scars. Besides, the results are far from perfect, as recurrences are frequent, since surgery alone, no matter how skillfully applied, can not eradicate the disease in its entirety. In joint tuberculosis, the plaster cast aims at an immobile joint and possible ankylosis with the hope of keeping the tubercle bacillus quiescent and thus stop it from causing further destruction. The aim of the combined x ray and quartz mercury lamp treatment is not only to keep the tubercle bacillus quiescent, but to stimulate all the immunizing forces of the body to fight the invader with the hope of its ultimate destruction. The results obtained from the newer method of treatment are arrived at in a much shorter time, are at least as good, if not better, and are the least disfiguring. Rieder says "with a high degree of certainty, we cure at present the socalled surgical tuberculosis of bone, joints, and lymph glands through means other than surgical."

Röntgen rays have been used with good results in the treatment of tuberculosis by Schiff, Holzknecht and many others as early as 1897, but it was after an improved technic in 1910 that such brilliant results were reported in Europe. The first group of cases which were treated with the better technic were reported by Iselin. Out of forty-one cases, twenty-four were cured and the rest markedly improved. In joint tuberculosis, Kohler obtained seventy-three per cent. cures with movable joints and the balance were cures with ankylosis. Stromyer reported thirty-nine cures out of forty-six cases of hip joint and knee tuberculosis. Rieder obtained fifty-two cures in a group of sixty cases.

Gratifying results have been obtained in other forms of tuberculosis. In tuberculous peritonitis the results are good. In those with ascites, aspiration of the fluid before treatment is necessary. In intestinal tuberculosis, especially in early cases, very good results have been reported. Those associated with lung tuberculosis yield poorer results. Even in lung tuberculosis the x rays have a marked healing effect, when the treatment is combined with the ultraviolet light or heliotherapy, and other supportive treatment. In tuberculosis of the bladder, Wetterer cured seven cases and eight out of a total of fifteen were improved. He advocates filling the bladder with protargol solution before the treatment in order to obtain a better deep effect. Schmieden obtained fifty per cent. cures in tuberculosis of the testicles, prostate, and seminal vesicles. In tuberculosis of the kidney, x ray treatment is the only thing to be considered, if both organs are involved. In tuberculosis of one kidney operative measures are to be considered from the viewpoint of preventing a systemic invasion. Even after removal of one kidney, the other kidney and the bladder should receive irradiation, because they may be tuberculous and no harm will result, as neither the kidney nor the bladder epithelium is injured by the therapeutic dose of röntgen rays. It is at present the recognized

*Read at a meeting of the Bronx County Medical Society, October 17, 1923.

method of treatment in all forms of skin tuberculosis, with the exception of lupus planus.

CASE REPORTS

Case I.—The patient, an eight year old boy, was operated upon by Dr. A. A. Berg for a suppurating appendicitis. He was discharged from the hospital before the skin wound was entirely healed. During his stay at home, the wound ulcerated and swellings appeared in each groin. He was readmitted to the hospital on January 20th, about two months after the operation. There was a slight discharge from the wound and its base was covered with whitish, unhealthy granulations. A bluish red, slightly fluctuating mass was present in each groin. They broke down a few days later, discharging a thick yellow pus, each leaving in its place an ulcer, the base of which was grayish and necrotic. There was no attempt at granulation. Two months later, a similar swelling appeared about the outer edge of the right pectoral muscle. This also soon broke down. The patient was emaciated. He was very weak and unable to walk. His weight was fifty-two pounds. His heart and lungs were negative. A small section taken from one of the ulcers revealed the pathological findings of granuloma with necrosis. No tubercle bacilli were found. His blood was negative to the Wassermann test and the wound discharge was negative to sporotrichosis and blastomycosis. Von Pirquet reaction was positive.

A clinical diagnosis of scrofuloderma with tuberculous adenitis was made, regardless of the inability to find the tubercle bacillus and treatment was instituted for that condition. He received one quarter of a skin unit of x rays once a week for the first four weeks. This was alternated with quartz mercury lamp exposures. The whole body was irradiated for from two to five minutes from a distance of fifty centimetres. The character of the lesions soon changed and healthy granulations made their appearance. The patient gained six pounds. He felt much stronger and was able to walk. During the following three months he received only one x ray and three quartz mercury lamp exposures each month, and was discharged cured on July 9, 1923, after making a further gain of five pounds.

Case II.—This patient was a girl, eleven years old. Pain and swelling developed in her right knee about five years ago, and her case was diagnosed as tuberculosis. Perhaps two out of the five years she had had to wear a cast. About a year ago, during one of those intervals when the cast was off, she fell and hurt her knee. It became swollen and gave all signs of fluid in the joint. She was again placed in a plaster cast, which was on for about three months when the patient and those about her began to notice a peculiar, offensive odor. This became so unbearable that the people, of their own accord, removed the cast and a broken down abscess on the inner side of the knee was found. For a long time the family physician attempted to heal the wound by cauterizing it, but failed.

I saw her first on October 1, 1923. She was fairly well nourished and weighed eighty-nine pounds. To all appearances her lungs were negative. She walked with a rigid knee, although it could be slightly flexed by force. It was somewhat painful and there was a certain amount of swelling about the joint. This was in the nature of an infiltration without any fluctuation. There was a sinus at the inner and lower portion of the knee, the edges of which were covered with exuberant granulations.

The patient received one fourth of a dose of hard filtered rays to the front of the knee, followed in three days by a general exposure to the quartz mercury lamp. The same process was repeated the following week. After two weeks the discharge completely ceased, the sinus was covered with a hard adherent crust, and the swelling about the joint was practically gone. She was able to bend her knee to a right angle, without any discomfort. There was complete absence of pain and tenderness. She gained three pounds in that short period.

These surprisingly rapid results were probably due to the fact that the lesions in this case were of the hypertrophic and granulating type, and as that type of tissue is a rapidly growing one, it is very susceptible to the action of the rays.

The rays have no direct action upon the tubercle bacillus. They have, however, a strong influence upon the general economy and on the process of antibody formation. Healing takes place by the destruction of the epithelioid cell and the lymphocyte and by causing an inflammatory reaction around the lesions. Minute fibres are seen to push into the centre from this surrounding zone and, in time, the whole process ends in fibrosis. The dose of rays must be carefully gauged so that the two processes, destruction and stimulation, may take place side by side. This is made possible by the fact that the tuberculous tissue is more susceptible to the rays than the normal fibroblast.

In the treatment of tuberculosis all efforts must be exerted towards the possibility of increasing the fighting power of the system. Therefore, x ray treatment of tuberculosis must be combined with all the other known useful methods of treatment, and a large part of what the x rays lack in efficiency is supplied by the rays of the quartz mercury lamp. These make an ideal combination, if skillfully applied. The two great qualities of the rays of the quartz mercury lamp are their powerful germicidal action and the great tonic effect which they have upon the entire system. Under the influence of this light, hemoglobin gives up its oxygen more readily, thus increasing the oxidizing power of the system. It lowers the rate of respiration and increases its depth. It increases the volume of the heart beat. It is refreshing to the patient. It increases appetite, promotes sleep, and causes an increase in body weight. Its other qualities are the change of oxydase into melanin, it is capable of splitting albumens, fats and sugars in the presence of catalytic agents, and may produce pronounced changes in the spleen.

Whether the rays act by way of the internal secretions of the skin or its action may be attributed to the oxydase and melanin changes, is not yet understood.

The ultraviolet rays of the sun lamp occupy a position in the spectrum midway between visible light and the röntgen rays, the shortest ultraviolet rays overlapping the longest x rays. It is also likely that they overlap in their biological action.

1955 Grand Concourse.

Historical Medicine

A Psychohistorical Study of the Sex Balance in Greek Art*

L. PIERCE CLARK, M.D.,
and HERBERT R. CROSS, Ph.D.,
New York

(*Continued from page 157*)

Ancient sophistications are shown in that the lawgivers like Minos of Crete claimed that if men sought only women, the lands would soon be overpopulated. Hence it was policy to encourage men to seek one another part of the time. On the other hand, military men contended that if armies were made up of pairs of lovers it would increase bravery, for while a soldier might run away to save himself he could hardly leave his male sweetheart in danger. This is said to have been the composition of the Theban sacred band who fell to a man in the battle of Cheronaea.

Artists recognized the bisexual idea, for they asserted that the most beautiful male figure had something of the feminine and the most beautiful female figure something of the masculine. Minerva, Diana and even some of the Venuses show maleness of contours, while Apollo is almost girlish.

FIG. 13.—Head of the Fanciulla d'Anzio, Musseo Nazionale, Rome. Whether this figure represents a boy of rather effeminate type or a girl of rather boyish character has been much disputed. The flat chest is distinctly male but the "Venus necklace" of the neck is emphatically female.

The only hostility found against homosexuality is limited to one ancient reference to Laios and Chrysippus who were punished by Hera (Juno), the goddess of marriage, for homosexual love; the provision in the laws of Solon which punished slaves who practised homosexuality was death; certain laws against or hostile to male prostitutes who took money, for these were looked upon like female public prostitutes. The genuine homosexual never took money from his male lovers although often he received costly presents. He was supposed always to be a perfectly free agent and to be actuated solely by choice. Nevertheless in the oldest records the man enamored of a boy always kidnapped him, in Crete and perhaps also in Chalcis. This was an echo of the custom of marriage by capture. Apparently it was only a ceremony. The fact that according to the legend Jupiter himself kidnapped the boy Ganymedes seemed to satisfy the Greeks that this character typified the boy object of homosexual love. The alleged kidnapping occurred at or near the town of Chalcis, which was so noted for homosexuality that the verb chacidizein meant to commit pederasty. The word Ganymede became a symbol of the passive rôle in the same act (corrupted in the Middle Ages to catamite). The relationships usually were of several different types as young or older men with boys and youths, or young men of the same age who were of somewhat different temperaments, with each other. The Greeks regarded the friendship of Achilles and Patroclus as homosexual, the latter being the passive partner. When Agamemnon stole a girl away from Achilles he sulked and refused to fight, but when Patroclus fell he was aroused to fight. His language to and about Patroclus struck the Greeks as homosexual. There is no indication that homosexuality was a reciprocal affair; one had a male passion and the other submitted. Most of the poets wrote passionate love odes to beautiful boys and it is said that homosexual love was represented in some of the best dramas, both Aeschylus and Sophocles representing it. We read that Pericles, who was a lofty idealist, repudiated homosexuality. It seemed to be a matter of purely personal sentiment and did not reflect the spirit of the age. It is said that when a fellow officer praised the beauty of some of the boys Pericles told him "a general should have clean eyes."

The fact that the leading conductors of philosophic schools defended homosexuality—men like Isocrates and Parmenides—shows how the public opinion of the day ran.

It is said that Phaedo, whom Plato immortalized, was originally a poor boy prostitute, who having been a war prisoner had according to the custom of the time been sold to the highest bidder for purposes of prostitution. After he had lived this life for a time a friend of Socrates and Plato bought him and set him free. A defense of homosexuality by one of the philosophers of the period was that "some desires are too strong to be resisted."

It appears that the boys who were the object of the passion were of a feminine makeup, but one author states that at a certain age there is little difference between the sexes which could hardly be distinguished save by the clothing. The glance of the eye, the complexion, the smooth face, the voice, etc., were the same in both sexes. It must be remembered that the Greek boys were of exceptional beauty.

Still another explanation of homosexuality by an ancient Greek (Plutarch) blamed the custom on the habits of the day in going naked in the gymnasia. In both sexes most of the bodies were exposed and there was more or less subconscious sex confusion. This is a popular explanation for the practice of homosexuality in prisons and in naval service even to this day, and is an obviously specious explanation.

Some writers such as Symonds[1] considers the subject of Greek inversion from an unusual angle

*Presented before Historical Section, New York Academy of Medicine, November 30, 1923.

[1]Symonds, J. A.: *A Problem in Greek Ethics.*

showing there were two quite separate forms of it at the outset. One was gross and sensual and reached Greece from Phoenicia, appearing first in the islands (Crete, Cyprus). The other was chaste and originated among the North Greeks or Dorians, the most hardy and continent of all the Greeks. In time the chaste form became merged into the other in such manner that it is extremely hard in individual cases to discriminate. The same word paederasty was applied to both forms as it meant simply boy love without necessarily connoting any gross sensuality. That this honorable form had originally been in existence is evident from certain passages reprobating the practices of the Cretans, Corinthians and Lesbians, as well as from the fact that the great attention to the question of personal hygiene by the Dorians, notably the Spartan discipline, would have made a life of sensuality out of the question. The Dorians were notably virile and no trace of any effeminacy is apparent in the boy objects of love. Every heroic figure among the Greeks both in mythology and history had a chum to whom he was devoted and the only way in which these friendships differ from those of the Anglo-Saxons was that one member of the team was the lover and the other the beloved. The Greeks called them the Inspirer and the Hearer. This connoted some superiority on the part of the Lover, who was older or had a higher rank or greater prestige, apparently. The basic idea or background was military life and the basic sentiment a sort of chivalry, this also implying that the Lover was in some way superior to the Beloved. The historical ideal was the friendship of Achilles and Patroclus and the prototype in the mythological world was the kidnapping of Ganymede by Jupiter, said to have been an invention of the Cretans to sanction their own unusual practices. It has been shown that Homer had no conception of any inversion among men; that interpretation of the friendship of the two men was given by Aeschylus and Sophocles.

Honorable boy love played an immense rôle in Greek history because in all political revolutionary movements teamwork of this kind is in evidence. Apparently when two chums devoted to each other conspired to kill a tyrant the plot went through. Of numerous instances of this kind the slaying of Hipparchus by Harmodius and Aristogition was the most famous although only one of a large number. A man could seemingly show a higher degree of fidelity and trustworthiness toward his pal than to any other man or group. If two lovers conspired to do a thing it was usually done. In a few cases when the plot failed both lovers suffered martyrdom; one would never see the other perish alone. The relationship was peculiar in another striking way. One lover always "stood for" the other, and if one was involved in any kind of disgrace his friend was also disgraced, although he had no hand in the offensive act. This must often have proved a restraining influence in life.

As the *Iliad* really rests on the love of Achilles for Patroclus so the other great epic myth of the Greeks, the war of the Seven against Thebes also had its origin in homosexuality. Laios, the father of Œdipus, kidnapped the boy Chrysippus, the son of Pelops, and the feud was thereby inaugurated.

The boy god Eros was the one who inflamed a man with love for a boy, as Aphrodite had charge only of the heterosexual love of man for woman.

After boy love had become corrupt in a high degree and was no longer a good influence it was tolerated despite its gross aspects and did not fall into disrepute until it was found to work in with all kinds of rascality in human dealings. It could be made to facilitate every kind of swindling, lead to feuds and murder, cause lawsuits, etc. Just as in irregular and unusual forms of heterosexuality in our times. Its final passing does not seem, as is generally supposed, to have been due to the advent of Christianity but only to the above factors.

When Athens was at the height of its power boy love had already become a serious problem, for it was necessary for a boy to have a chaperone for several reasons. A free boy was always accompanied by an old and trustworthy slave. He was obliged by custom to look straight ahead or down and anything like "making eyes" at people was frowned upon. Certain establishments he must never be seen in, as barber shops, florists and perfumers. If the boy was alone on the street he would be accosted and solicited. Any boy tempted to take money was ruined in reputation. There was no stigma attached to a costly present from a recognized lover.

Some boy lovers defended their course by drawing an unfavorable parallel between a well bred boy and the average woman who was frivolous and inconstant, ignorant, taken up chiefly with her toilet. The qualities attributed to a good well bred boy were of such high character that it seems to exclude gross lust. Incidentally he was distinguished for personal hygiene, keeping himself fit, etc. This view was probably an old Doric one.

Female inversion played no rôle in Greek civilization and was looked on as degeneracy. There was always an Amazonian virago in association with an overfeminine young girl whom she corrupted. There was never any attempt to dignify female inversion. However, Plutarch mentions that in Sparta respectable matrons often made love to young girls and formed attachments with them.

Licht[2] published a pamphlet on Greek love as found in the pages of the satirist Lucian, and makes original comments. Of the purity of the Doric form of homosexuality no one can doubt for a moment who has read the work of Bethé and others.

The classic Greek period was the golden age for boys and the boy and youth was the centre of the stage, everything revolving about him. As soon as he had attained a certain age his education was taken over entirely by men and the whole system—all that was done for him—had the single object of giving him a beautiful body. Hence of course the physical culture. Perfection of action presumably connoted beauty of form. Of the great heroes of mythology and prehistory many were noted for great physical beauty. Handsome youths were always in great demand on state occasions, as weddings and sacred dances. They were also needed as pages.

It was necessary for the object of love to be a parasite on the lover. Equals in all respects could not enter into this relationship. It seems to have

Fig. 14.—Hermaphrodite. Musseo Nazionale, Rome. Hellenistic period. The last step in the confusion of the sex balance. The ideal union in one body of the long hair, large breasts and soft contours of a woman, with the developed sex organs of the male.

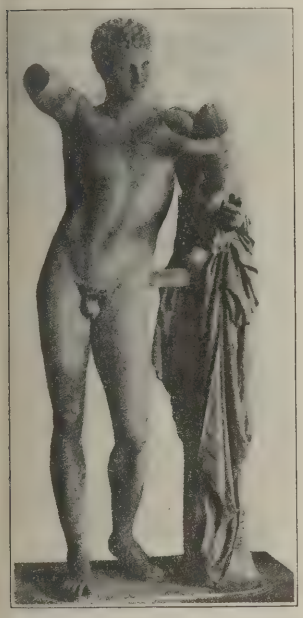

Fig. 11.—Hermes of Praxiteles. Fourth century B. C. A strong and muscular body but with such a veil of graceful languor thrown over it as to come very near to the point of effeminacy.

Fig. 15.—The Farnese Hercules in the Musseo Nazionale, Naples, Hellenistic period. An example of the reversion in late Greek sculpture to the primitive "cave man" type of masculinity.

been common for the object to be inferior in one or more respects. Often it may have been only in years but in some cases the beloved was low born, and perhaps an alien, who could not speak without some accent; or the inferiority was in wealth, this perhaps being very common while inferiority in rank was evidently also common. This inferiority naturally made a chivalrous relationship possible. The object was often of great beauty and perfection.

Whether the pure or impure form is thought of it is only necessary to visualize these attachments to imagine that the girl of heterosexual passion is replaced by a boy. Nothing is lacking that is found in heterosexual love. Not much is said of the attitude of women toward boy love but there is enough to show that they were very jealous of the boy rivals although we read of no tragedies from this cause.

Lucian was a scurrilous satirist who flourished between 120 and 180 A.D. Greek love had then become uniformly gross but even the homosexual lovers of the heroic ages did not escape his slurs. He was the first to use the "imaginary conversations" of dead with dead or dead with living to bring out situations.

There is a long dialogue in poetry between Jupiter and Ganymede which abounds in sensualism.

In a typical case of attachment to a boy, Lucian states that so absorbing is the passion that in the absence of the object the lover can only live with him in memory. All of his sayings and actions are called up in mind and the lover is as shut off from the outer world entirely. He forces himself to imagine that the object is acutally present. Polystratus fell in love with a boy who was an alien, a good for nothing, a barbarian who only spoke Greek with an accent, and made him his sole heir.

The general nature and treatment of the transference neuroses are no longer a mooted question. The principles and mechanisms underlying them are so well known that even the beginner in psychoanalysis may handle them successfully. But the conversion forms of the neuroses, the compulsive states with their ceremonials as well as morbid fears and obsessions, are not so easily handled. While hybrid forms of narcissism and homosexual neuroses, paranoid states, ill defined ideas of reference, and even hypochondria, all cluster about the disorders of the ego, they are in such confusion

Fig. 16. — Crouching Venus. Vatican museum, Rome. Hellenistic period. The reversion in late Greek art to the unmitigatedly feminine or "vamp" type.

Fig. 12.—Detail of the Apollo from Sutri - Musseo Nazionale, Rome. Hellenistic period, showing the extreme effeminization of the male figure. The softness and roundness of contours, the long and daintily arranged hair, the girlish features and prominent breasts make this Apollo little removed from the Hermaphrodite.

Fig. 10.—Theseus, from east pediment of the Parthenon by Pheidias. Second half of the fifth century, B. C. Very refined and beautiful but not in such measure as to overbalance the essential grandeur and masculinity.

that it is exceedingly difficult to isolate the types.

It may fairly be taken for granted that the general conception of the psychobiological formula of Freud as modified by Burrow explains the mechanism of homosexuality and its attendant neuroses. In brief, the substance of the theory is as follows: According to Freud, the two determining factors in the production of homosexuality are the love for the mother, and the love for one's own body. These two components—the mother-complex and the narcisissism—are invariably present and stand to each other in a relation of contrast, the narcissism being a consequence of the repression of the mother-ideal. That is to say, the person rids himself of the mother-image as object, by identifying himself with the mother and replacing her with his own person as the sexual object. Later, through an association of similarity, he extends his object to include other persons of his own sex. Thus we have the mother-complex giving way to narcissism as the first step, the narcissism yielding homoerotism or homosexuality as the second. Such are the factors and related mechanisms which have been offered by Freud to explain the development of the disposition to homosexuality. Burrow's modification, which is clearer, may be stated as follows: We find that the child, both male and female, is strongly identified with the body and person of the mother before and for some time after birth. At the time of birth it begins to reduce the oneness or identification with the mother, but before a full separateness is attained the child gradually swings its attitudes of attachment from the mother to its own body and person. It loves itself, not only because it is pleasurable and the immediate object at hand, but because the identification with the mother follows the love-concern of the mother, and that in the growing child's mind is the mother's love for his own body and person. When the subjective or mother-identification state exists beyond the average in strength and duration, the psychic system remains strongly infantile, emotional and introverted. If the child is a male, the tendency is to develop mentally in a feminine way; and if it is a female there is a tendency to develop mentally in a masculine way. Thus, if we may disregard the biological inheritance, there is a distinct psychological reason for homosexuality.

(To be concluded)

Contributors to the Science of Medicine

CHARLES McBURNEY, M.D.

Charles McBurney, one of the foremost figures in American surgery from 1890 to 1900, was born in Roxbury, Mass., on February 17, 1845. His father, who was of Scotch-Irish descent, came to this country when he was a boy and became a manufacturer. His mother was a descendant of old Maine and Massachusetts families. McBurney received his early education in the Roxbury Latin School and the Boston private schools. He received the degree of A.B. from Harvard in 1862 and of M.A. in 1866. In 1870 he was graduated in medicine from the College of Physicians and Surgeons of New York, and from that time until his retirement in 1907 he made New York City the field of his work. His first position was that of surgical intern at Bellevue Hospital. After serving for eighteen months in this capacity, he went abroad and studied surgery in Vienna, Berlin, Paris and London. Returning to this country, he began practising in New York in 1873, and a year later became associated with Dr. George G. Peters, with whom he remained until the latter's retirement ten years later. The list of important positions held by Dr. McBurney gives an outline of his professional career. He taught at the College of Physicians and Surgeons from 1873 until 1900, first as assistant demonstrator of anatomy under Dr. Henry B. Sands, then as lecturer on the anatomy of the nervous system from 1878 until 1880, as lecturer on operative surgery from 1882 until 1889, as professor of surgery from 1889 until 1894, and as professor of clinical surgery from 1894 until 1900. In 1875 he had been appointed attending surgeon to St. Luke's Hospital, in 1880 to Bellevue, and in 1888 was given charge of the entire surgical service of the Roosevelt Hospital, succeeding Dr. Sands, a post which he filled until 1900. Other positions held were those of consulting surgeon to the New York Hospital, St. Luke's Hospital, the Presbyterian Hospital, the Hospital for the Ruptured and Crippled, the Orthopedic Hospital, and St. Mark's Hospital. He was a member of the New York Surgical Society, the Practitioners' Society, the Roman Medical Society, and was a fellow of the Royal College of Surgeons of Edinburgh, a corresponding member of the Société de Chirurgie of Paris, and an honorary member of the Medical Society of Constantinople.

Dr. McBurney's most important work was done during his incumbency at Roosevelt Hospital. His workshop and laboratory was the Syms Amphitheatre, planned and built under his direction, and at that time the best surgical amphitheatre in the country. One of the many devices worked out there by him, in cooperation with Dr. Frank Hartley, was the modern steam sterilizer, now in general use. Aseptic surgery was at this time still in its infancy and through his efforts was raised to the high place it now occupies. It was through his experiments that it was demonstrated that rubber gloves were not only advisable but necessary for the surgeon and entire personnel of the operating room. His method of using dry gloves with armlets is now general. Dr. McBurney is best known as the discoverer of McBurney's point in the diagnosis of appendicitis. This is a spot located from one and a half to two inches from the anterior superior iliac spine in a line drawn

thence to the umbilicus. This is the usual situation of the base of the appendix and the place where localized pain and tenderness are almost invariably found in cases of inflammation. Deaver writes concerning McBurney's point that "it was a valuable advance, not so much because the pain in every case is just in that spot, but because it put into the physician's or surgeon's thoughts, in a practical, concrete way, a ready method of excluding every other disease with almost absolute certainty; and, though it is not always possible to deny the existence of appendicitis when pain and tenderness are in another place, it is a very rare thing for the signs to be circumscribed in this way and for the affection to be other than appendicitis." McBurney proposed also as early as 1893 the original gridiron or muscle splitting incision, since modified to gain more room in case of emergencies. Some members of the profession feel that McBurney's most important contribution to the treatment of appendicitis lies, not so much in the "point" or in the gridiron incision, but in what he did, in his writings and through constant and untiring effort in his clinics, to convince the medical profession that acute appendicitis is purely a surgical affection requiring immediate surgical care. Other permanent advances in surgical technic originated by Dr. McBurney are his tractor for reducing fracture dislocation of the shoulder joint; a small transperitoneal incision for the fingers of the assistant to compress the common iliac artery in disarticulation of the hip joint; the McBurney staff for rapid perineal section; his transduodenal method of removing stone from the common bile duct; and the McBurney hooks for skin grafting. As an operator he was supremely careful and accurate, so that the tissues received only the least possible injury, and it was never necessary to go over twice the same step or field. In rare and difficult cases he never operated in public. Among operations in which he was most interested were hernia, resection of the knee for tuberculosis, and amputation of the breast for carcinoma. To his patients he was always extremely gentle and considerate, and held their absolute confidence. Dr. Charles H. Peck writes of Dr. McBurney: "Although a good student of his specialty, Dr. McBurney was not a scientist in the restricted use of the term, but shone by his strong common sense in his attitude toward his patients. He could not have been called a 'brilliant' operator, but his lack of hesitation, founded on the care with which he planned every operation and the thoroughness with which he completed each step before passing to the next, resulted in a great saving of time and left the spectator with the profound impression that he had seen a master of his art at work. Bold, yet a great respecter of tissues, the finished result of his operations left little to be desired." He was a remarkable diagnostician, in spite of the utmost simplicity that marked his methods of examination. He was called as consultant to the bedside of President McKinley a few days before the latter's death.

Charles H. McBurney

As a teacher and lecturer, he was preeminently clear, simple, and practical. In his teaching, he made it a point to give thorough instruction in a few of the most usual, fundamental, and important medical subjects, rather than to take up rare or difficult cases and procedures that would seldom occur in his students' practice.

As a writer Dr. McBurney's most notable contribution to the literature is probably his classic paper on appendicitis, entitled Experience with Early Operative Interference in Cases of Diseases of the Vermiform Appendix, which was published in the New York Medical Journal for December 21, 1889. This article emphasizes the importance of McBurney's point. Other important contributions are Dislocation of the Humerus, Complicated by Fracture at or Near the Surgical Neck, with a New Method of Reduction (*Annals of Surgery*, 1894); Removal of Biliary Calculi by the Duodenal Route (*ibid.*, 1898); Use of Rubber Gloves in Operative Surgery (*ibid.*, 1898); Remarks Concerning the Practice of Aseptic Surgery (New York Medical Journal, 1902); Technic of Aseptic Surgery (*International Textbook of Surgery*), and contributions to Dennis's *System of Surgery*.

Personally, Dr. McBurney was much beloved by patients, staff, and colleagues. He was a man of great charm of manner and person and an able and dignified executive. He was a true sportsman and a great lover of outdoors and nature. His death, which occurred on November 17, 1913, at the home of his sister in Brookline, Mass., was from heart failure brought on by overexertion during a hunting trip in Maine.

OBESITY, BRAINS AND CHARACTER

There seems to be a conviction that the mere possession of superabundant adipose deposit endows its owner with good humor and good nature. Or rather, perhaps, that obesity and an equable temperament go together. Whether this combination is supposed to be the result of placidity and phlegm, in short, a state of bovine contentment, has never been clearly explained. For after all it is but a supposition.

True, the belief is probably as old almost as the hills. According to Shakespeare, Julius Cæsar held the view and said: "Let me have about me men that are fat," referring particularly to the danger that lurked behind "the lean and hungry look of Cassius." Fat men, while credited usually with good humor and good nature, are invariably denied the possession of any great intellectual capacity. It may be mentioned that in fiction there are fat men who are thoroughly bad and who have considerably more than their fair share of brains, as well as fat men who are good natured but not distinguished by intelligence. Count Fosco, in Wilkie Collins's *Woman in White*, is, perhaps, the best example in fiction of an immensely fat man who also contrived to be a thoroughly capable villain. His cleverness is insisted on throughout the story, as is also his ponderous bulk. Marion Halcombe, although she both feared and hated him, began by finding much that was charming in his personality. Her description of him and her views on obesity so well express the opinions of many that it will well bear quoting: "He is immensely fat. Before this time I have always disliked corpulent humanity. I have always maintained that the popular notion of connecting excessive grossness of size and excessive good humor as inseparable allies was equivalent to declaring, either that no people but amiable people ever get fat or that the accidental addition of so many pounds of flesh has a directly favorable influence over the disposition of the person on whose body they accumulate. I have invariably combated both these absurd assertions by quoting examples of fat people who were as mean, vicious and cruel as the leanest and worst of their neighbors. Holding these strong opinions as I do at this moment, here, nevertheless, is Count Fosco, as fat as Henry the Eighth himself, established in my favor at one day's notice without let or hindrance from his own odious corpulence."

However, Miss Halcombe found that Count Foscoe's cruelty and viciousness were concealed, when he desired, under the mask of a charm of manner which revealed to those who saw the mask withdrawn, the infinite subtlety and cleverness of the man. Fiction abounds with men and women who were fat and clever and of strong character, who were fat and mean and vicious, who were amiable nearly to idiocy, and who were just ordinary individuals. It is no doubt much the same in real life. There is another aspect or a variation of this aspect of the matter, which is that of obesity and genius often allied. Theophile Gautier once brought forward this question in one of his inimitably, frivolously witty essays with an understratum of truth. As Gautier himself was a genius or near akin, his words are entitled to attention. Perhaps, too, Gautier, who himself was a mountain of flesh, was swayed by that fellow feeling that makes us wondrous kind. Among those he mentioned and poked fun at, although the arrows were somewhat barbed, were Victor Hugo, Balzac, Dumas, and Rossini contemporaries, and undoubtedly geniuses and who were of abnormal obesity, in the case of Dumas of abnormal proportions. Gibbon, the great historian, was so corpulent that when he fell on his knees to Madame de Crousaz, she had to ring for the servant to help him to rise. Thomson, the poet of *The Castle of Indolence*, described himself as "more fat than bard beseems," and Leigh Hunt said of Gay, the author of *The Beggar's Opera*, that he was "a pleasant climax of obesity." William the Conqueror, a military genius, was of immense proportions and carried an undue weight of fat.

There is no especially close relationship between obesity and genius, but, on the other hand, the burden of "too too solid flesh," which Falstaff bore, does not preclude the possession of genius, brains, character, or meanness, viciousness, duplicity, or all the vices and ignoble traits.

It is probable that some of the instances of obesity referred to above were developed if not caused by the habits of life. Given a predisposition by heredity, Futcher has traced a clear history of heredity in sixty per cent. of his cases, the manner of living and especially of diet of men as Victor Hugo, Balzac, Gautier, Gibbon, and Gay will largely account for the increase of fat. They led essentially sedentary lives, were selfindulgent, or careless of their diet, and, in the case of some, large eaters of rich food and imbibers of good wine. Then again, the question of race must be taken into consideration, the Dutch, South Germans, South Italians, and the natives of India and Ceylon are all inclined to obesity. Count Fosco was an Italian. The influence, too, of the ductless glands has much to do with

corpulence. For example, there are two clinical conditions in which the thyroid plays an important part in hypothyroidism and hyperthyroidism. The person with hypothyroidism tends to increase in weight and the basal metabolism is much lower than usual. In hyperthyroidism the reverse is the case. When the basal metabolism is low, it is obvious that the person will tend to get fat. The action of the other ductless glands is not so well understood, although when the posterior lobe of the pituitary gland is damaged by a tumor, considerable changes take place in the metabolism and weight is put on.

The gonads also have much influence on metabolism and consequently on body weight. There is no relationship between obesity and genius, cleverness, or character, although, all else being equal, the placid person of either sex, who has, perhaps, a tendency to hypothyroidism, is more likely to become unduly fat than the restless individual, who has a tendency to hyperthyroidism. According to Dr. Hyman Goldstein, writing on The Rôle of the Endocrines in the Growth and Nutrition of Children, states that thyroid insufficiency produces the lazy, obese and constipated type of children. He also says that they are sluggish mentally. Is this always the case or does the mental sluggishness depend upon the degree of hypothyroidism? If thyroid insufficiency signifies obesity and dullness of intellect, then the men of genius, the clever men whether rascals or otherwise, did not gain their surplus fat by hypothyroidism.

This is a fine point. There is yet much to be learned concerning the action of the endocrine glands and it is more than probable that obesity is intimately related to inefficient working of these glands. In any event, because a man is inordinately fat does not prevent him from being inordinately clever or a genius, nor in the very nature of things is it essential that he should be easy going.

LITERATURE AND MEDICINE

Many medical men in all countries have been literary men as well, some of them distinguished writers on subjects outside their own province. Some have introduced a true literary flavor into their medical and surgical writings, although it must be confessed that there have been and are few members of the medical profession who have written or who write in a cultured manner and especially of the English speaking branch of the profession. A large number in this country appear to think it a sign of effeminacy to express their views in good English, but pride themselves somewhat on the use of the vernacular, protesting that all that matters is that their readers should understand what they write easily and clearly. There is no doubt that this is a mistaken mode of regarding the question, as a well expressed, well written article will carry more weight than one written carelessly.

The old time doctor was perhaps from the literary viewpoint in certain respects better equipped than the modern prototype—he had to know Latin, although, of course, in many instances the knowledge was superficial and indeed a prostitution of a noble language. Latin was used among lettered physicians when medicine was made a mystery by its professors and every endeavor was put forth to keep it so, and for a doctor to speak in a foreign tongue aided in the assumption that he was a being apart and suitably impressed the public.

Mr. Edmund Gosse, the well known writer and literary critic, who delivered the first David Lloyd Roberts Lecture at the Royal College of Physicians, London, on November 20th, pointed out that in those days it was as indecorous for a medical man to discourse of physic in any language than Latin as to walk in the streets without a wig, although it was in the same period that Voltaire uttered his bitter jibe that doctors poured drugs of which they knew little into human bodies of which they knew less. But the greatest of ancient physicians were conscious of literary form—Hippocrates for instance, was careful to write simply and clearly, seemingly that women and girls should be able to understand his meaning. Ambroise Paré, the great French surgeon, who, probably modelling his style after the incomparable Greek physician, ostentatiously wrote in his own language, had a direct influence in accustoming English speaking physicians and surgeons to express their views in English. It may be mentioned, however, that Paré's daring in this respect was highly resented by his fellow physicians who tried to suppress his works on the ground that their terms were intelligible outside the profession.

In this country and in Great Britain long after the time of Paré, doctors continued to wear wigs, to employ indifferently good Latin and to carry gold-headed canes, to pose, in fact, as the mysterious medicine man. Sir Thomas Browne of immortal memory with the divine gift of language and ecstasy—and Locke, the friend of the practical, keen witted Sydenham, with his tolerant candor brought the various professions together in a unison which could never be broken up again into the discord of the Middle Ages. At the end of the seventeenth century the barrier between imaginative literature and medical science was broken down once and for all, since when there has been a sprinkling of medical men who have made something of a name in literature.

Those of the seventeenth century were not in the front rank or near the front rank in literature. And

of those of the eighteenth century Oliver Goldsmith, who shed lustre on literature and was the shining light of his time as a literary man, was hardly known as a medical man. Mark Akenside was an excellent anatomist and a passable poet, while Tobias Smollet was a splendidly vigorous writer, but as a surgeon-apothecary was of little repute.

The truth is that medicine and literature are jealous mistresses, who exact the best in a man to excel in either, that there seldom have been men who have won lasting fame in both spheres. Perhaps our Oliver Wendell Holmes may be cited as one of the very few who have done so. He was distinguished and original as a physician, but even his fame rests rather on the literary output than on any work he did as a medical man. Yet there has been always an identity of sympathy between doctors and men of letters not to be found between medical men and members of other professions. It may, too, be stated with emphasis that a good education is not a handicap to a medical man, as is said by some carping critics, and that to be able to express himself in well phrased English is a decided advantage. In short, it is not incompatible to be at one and the same time, a literary man, even a highly cultured literary man, and an able and skilful physician or surgeon.

GASTROENTEROPTOSIS AND ITS CAUSES

The treatment of gastroenteroptosis is frequently somewhat of a stumbling block to the surgeon, that is, the selection of cases suitable for operation. Overenthusiasm for a certain operation often does more harm than good as it may and does lead to its adoption in unsuitable cases by surgeons who have more courage than judgment, thereby discrediting in the eyes of the conservative surgeon an operation which is found eventually to be of the highest value. Operations, which, when first introduced, were found to present many and great difficulties, are now standardized and practised after plan with little difference in technic by surgeons in all parts of the world.

The momentous question is to choose the cases suitable for operation. This phase of the situation was emphasized not long ago by Mr. James Berry, of London. He pointed out that the facility of operation was in some respects almost a menace because it led to operations being performed by surgeons of little skill, experience or wisdom, with the result that a particular form of operation has been discarded not on account of any technical defects, but because it was unsuitable in an individual case. For such reasons, as Sir Berkeley Moynihan points out in an introduction to Dr. Robert C. Coffey's recent monograph on gastroenteroptosis, the whole subject of visceral prolapse has been discredited in the minds of many physicians and surgeons. There has perhaps been too much surgical adventure in such cases. Coffey, in the preface to his book, reviews the work on stasis and ptosis in a most thorough and searching manner. He refers to investigations and clinical work on the subject by Rovsing, Lane, Longyear, Richard Smith, Goldthwait, Franklin Martin, Klose, Wilms, Waugh, Jackson, Walton, Klemm, Blake, and others.

Coffey deals with the work of Lane more than with that of anyone and draws attention to the fact that Lane has taught most of what is known of the end results of stasis and of the nature of the acquired bands found in the abdomen. His law, Coffey holds, of the crystallization of the line of force is probably the most important observation that has been made in connection with the subject. He thinks, however, that he has failed to recognize the importance of the normal prenatal fixations of certain abdominal organs and that deficient prenatal fixation was the underlying cause of much of the membranous development. In the book, also, the work that N. Mutch did under a grant from the British Medical Association on the bacteriology of the gastrointestinal tract is summarized and this report appears to justify Lane's statements as to the menace of chronic intestinal stasis.

As for treatment, Coffey lays down his views as to the general indications for surgical treatment, which, in the main, are conservative. He regards gastroenteroptosis from the anatomical rather than from the physiological aspect and believes that enteroptosis depends to a large extent on whether the normal peritoneal fusions have taken place during embryonic life. It is on this point that Coffey chiefly differs from Lane in his views the latter taking the stand that the bands and other mechanical deviations from the normal are acquired. Coffey is convinced that, once displaced, the abdominal bands, which are the chief defence of the organism against falling and further falling of the viscera, give rise to abdominal symptoms. He is, moreover, of the opinion that merely dividing these bands is a comparatively useless procedure and can only afford temporary relief, the bands becoming fixed as strongly as ever. He bases his treatment on the proper fixation of the dropped viscera and division of the bands which do not reform when the viscera remain in their normal position, where they will remain if they are fixed securely.

Coffey, then, is of the opinion that chronic intestinal stasis is by no means responsible for all the anatomical changes which bring about gastroenteroptosis, although he allows that to stasis is partly

due the condition, while Lane insists that it is owing to long continued intestinal stasis that enteroptosis ensues. Other authorities take Coffey's or Lane's views or modified views on the matter. But even allowing that chronic intestinal stasis is only responsible, in part, for gastroenteroptosis, would it not be wise, as far as possible, to prevent stasis from developing, that is, to treat it in its early stages by diet, exercise, and so on. There is no doubt that the secret of success in medicine lies in early diagnosis and efficient preventive treatment. The difficulty is that persons do not consult the physician, as a rule, until they feel really sick, or, if they do, obtain medical advice for a minor ailment. They do not follow the advice for long, but quickly lapse into their habitual mode of living. The public need to be educated in medical matters and especially as to the wisdom of seeking medical advice when out of sorts; if this were the custom, cancer and many other chronic diseases and, perhaps, gastroenteroptosis, would be far less common than at present.

SUN TREATMENT OF TUBERCULOSIS

It is beginning to be generally believed that the remedial and even curative properties of the sun are almost illimitable. Certainly, the light of the sun is the most potent agent in the field of preventive medicine. Lack of sunlight is responsible for various diseases and conditions of ill health and its rays, unimpeded by clouds of dirt, so often the case in London and in other industrial cities, exert a remarkably effective healing power. There are two diseases which are strikingly amenable to the action of sunlight, tuberculosis and rickets. For long it was held that diet was the important factor in the successful treatment of these maladies, but these views have changed considerably and, in the opinion of the best known authorities on tuberculosis, sunlight takes the first place, and with regard to rickets opinions are veering in the same direction.

The most marked results of experience of sunlight as a curative agent is to be witnessed at the world famous clinic of Dr. Rollier, at Leysin, Switzerland, which has become a Mecca for those closely concerned with the tuberculosis problem. Dr. Agnes Savill discussed Leysin and the treatment carried on there at a meeting of the London Association of the Federation of Medical Women on December 11th last. Dealing with the scientific aspect of the treatment, the physical properties of light with its bactericidal and chemical powers were discussed. It was pointed out that the ultraviolet rays, though apparently of low penetrating power, yet seemed of great therapeutic importance, and it was suggested that their wave length might be modified by passage through the pigment containing basal layers of the epidermis.

An interesting point on which Dr. Savill insisted was that the good results were due to the sunlight itself, rather than to the pure air and good conditions. This was indicated by the fact that results seemed to be distinctly poorer in cloudy weather and also that very severe reactionary effects could be induced by improper or careless dosing. It must be emphasized that light, like any other therapeutic agent, requires careful regulation, the dose being studied for the individual and based on the measurement of definite reactions, rise of temperature, dermatitis, exhaustion, etc. It was worthy of note, too, how health was maintained by the action of the light alone, the patient being entirely at rest, and no massage being used. Dr. Savill then discussed the various artificial substitutes with which she was acquainted and ended by stressing the need for accurate doses of sunlight, for a pure atmosphere, and for a lengthy treatment, if a successful result was to be anticipated.

Dr. Helen Mackay, who studied rickets in Vienna during the war, while the conditions there were peculiarly favorable for such investigations, described her experiences from the experimental side of the question, both in Vienna and at the Infants' Hospital, London. Dr. Mackay was deeply impressed with the value of sunlight in the treatment of rickets. The discussion was exhaustive and dealt with the relation of pyorrhea alveolaris to sunlight and the questions of the relation of impure air to tuberculous cervical adenitis, the advisability of improving the health of the school child in this respect and also the practical side of treatment and the type of patient who is most likely to be benefited by the treatment.

The harm done to health by dirty and smoke laden atmosphere in industrial areas is now acknowledged and it is recognized that one of the longest steps towards eradicating disease is to improve the environment of the town dweller and to render the air of crowded industrial centres as pure as possible. A smoke laden atmosphere, besides being unhealthy in itself, does its greatest amount of injury by preventing the light of the sun from reaching those who live where such conditions more or less prevail. Fortunately, in American cities the air is generally clear and relatively unpolluted, but in many the sun is not given the opportunity for fully diffusing its disinfecting, invigorating effects because of elevated railways, narrow streets, and high buildings. Light is life and lack of it causes ill health. The therapeutic virtues of sunlight can scarcely be overestimated.

FREE INSULIN IN ONTARIO

Dr. Forbes Godfrey, minister of health of the Province of Ontario, made one of his first official acts a formal decree announcing that his department would provide free insulin for all diabetics in the province unable to pay for this treatment. "I want to put the workingman of Ontario in the same caste, as regards health, with the millionaire," said Doctor Godfrey, who is a Conservative, succeeding in office a Farmer-Labor minister, so his humanitarian act has been called communistic and even revolutionary. The condition attached to the free receipt of insulin is a certificate from the applicant's physician stating that the former is unable to pay for the remedy.

The source of the supply for the province is the Connaught Laboratories of the University of Toronto, which are really nine laboratories at various places, all under Government control. Each of these laboratories is being equipped to furnish a supply of insulin and to afford the treatment for physicians in their respective localities. The University of Toronto, cooperating with the Toronto General Hospital, gave last summer short courses in treatment by insulin, to which general practitioners, especially from the rural or semiurban districts of Ontario, flocked in large numbers to be the better fitted to serve their public. Through these physicians and the nine Government laboratories, it is reported, 161 needy patients received a total of 114,000 units of insulin at a cost to the Government of $2,281, during the first month, September, of free distribution. In October the number of units was increased thirty-three per cent. and the number of patients as well. Six new distribution centres were added. Yet only a small proportion of the cases of diabetes in the province in a stage where insulin may be effectively used were reached, for the total of such cases is estimated at at least one thousand. This humanitarian act of Ontario and of Minister Godfrey is one to be emulated elsewhere.

JAPANESE EARTHQUAKE RELIEF

An interesting account of the rapidity and efficiency with which the Japanese rallied and devoted their best efforts to relieving the frightful conditions brought about by the late earthquake is given in a recent issue of the *World's Health*. The first action of the Government was to appropriate a sum of two hundred and sixty-five million dollars for relief work. A committee called the Imperial Japanese Earthquake Relief Committee was formed with the Prime Minister as chairman. The devastated areas were placed under martial law, and the Government arranged to sell supplies at cost to those who could afford to pay, using the proceeds for distributing free articles to the destitute. The Japanese people themselves raised fifteen million dollars by voluntary contribution, in addition to large gifts from the Imperial family and the Government. The Japanese Red Cross began work on the day of the earthquake with a sum of two million five hundred thousand dollars for their work. Since their headquarters had been burned, they established a temporary office in the Red Cross Hospital at Shimoshibuya and mobilized all the staffs at the branches throughout the country, as well as those of the Manchurian and Korean branches, instructing them to organize at once relief contingents. This was done and parties were sent out, one after another, to the devastated districts. The society constructed in Yokohama and Tokio temporary hospitals with accommodations for fifteen hundred cases. As regards precautionary and preventive measures, the society organized mobile relief columns, centres for rapid detection epidemic or contagious diseases, the transport of patients, and the carrying out of other measures for sanitation and disinfection.

Some of the nations cooperating in the relief work were the United States, Australia, Canada, Cuba, Ecuador, France, Great Britain, Holland, Italy, Poland, Russia, Switzerland, and Sweden.

Obituary.

SIR JOHN TWEEDY, F.R.C.S.

London, England

The best known ophthalmic surgeon in Great Britain, Sir John Tweedy, died in London after a short illness at the age of seventy-four. Born at Stockton-on-Tees in the north of England, Sir John received his medical training at University College medical school and hospital and became qualified in 1872.

He took up ophthalmic work and became a clinical assistant at Moorfields Ophthalmic Hospital in 1874. In 1879 he was elected an assistant surgeon at Moorfields, and in 1886 was made full surgeon. In the meantime he had been appointed assistant ophthalmic surgeon at University College Hospital and professor of ophthalmic medicine and surgery. From 1885 to 1904 he served on the staff of University College Hospital and on his resignation was appointed emeritus professor. He had been elected a Fellow of the Royal College of Surgeons in 1876; in 1892 he became a member of the Royal College of Surgeons and eleven years later president. He also served as president of the Ophthalmological Society of the United Kingdom of the Royal Medical Benevolent Fund and of the Medical Defence Union. Sir John Tweedy was greatly interested in medical politics and worked hard for the good of the profession. He was largely instrumental in the introduction of some necessary reforms. In 1906 he received the honor of knighthood and in the same year the University of Edinburgh conferred upon him the degree of a honorary LL.D.

Tweedy was an extremely clever writer and a journalist of the first rank. He was a prominent member for many years of the staff of the *Lancet*. Indeed, at one period of his life, it was a question with him whether he should not devote himself wholly to journalism rather than to practice. He was a friend of the Walsleys, who owned and edited the *Lancet* up to fifteen years ago. A month or so ago he was at the centenary dinner of the *Lancet*, although he was then feeling far from well. But loyalty to the journal with which he had had such intimate ties for years prevailed and he joined in the celebration probably to a considerable detriment of his health.

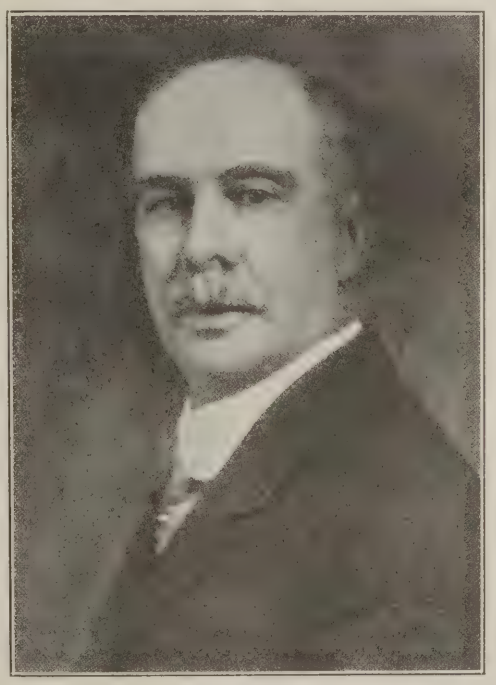
As well as being a skilful surgeon, Tweedy was a man of great administrative capacity whose advice was much sought and valued. In private life he was loved and highly respected by a large circle of friends.

LEWIS SAMUEL McMURTRY, A.M., M.D., LL.D., F.A.C.S.,

Louisville, Ky.

Dr. Lewis Samuel McMurtry, one of the great specialists of his time in gynecology and abdominal surgery, died from pneumonia at his home in Louisville, Ky., on February first.

He was born at Harrodsburg, Ky., in 1850. When he was still quite young, his parents moved to Lancaster, Ky., where his boyhood was spent. In 1870 he was graduated from Central College, and three years later received his degree of M.D. from the branch of Tulane University at New Orleans. He spent two years thereafter in clinical studies at the Charity Hospital, New Orleans, then went to Danville, Ky., and located, practising successfully there for several years. Later he came to New York for laboratory and clinical work, and also went to Europe for the study of surgery and gynecology. In 1889 he located in Louisville, where he limited his practice to gynecology and abdominal surgery. He occupied the post of professor of gynecology and abdominal surgery in the Hospital College of Medicine, later merged with the medical department of the University of Louisville. Among other honorable positions held by Dr. McMurtry were those of surgeon to the Louisville City Hospital, and to the Norton Memorial Infirmary. From 1905-1906 he was president of the American Medical Association. In 1909, Tulane University conferred upon him the honorary degree of LL.D. He was a member of the American Gynecological Society, with the rank of active fellow. He was also a fellow of the British Gynecological Society and of the Obstetrical Society of Edinburgh. He was one of the founders of the International Congress of Gynecology and Obstetrics, and his work won wide recognition, not only in the United States, but in France and the British Isles. At the time of his death he had served for five years as president of the State Board of Health of Kentucky. His wife was Mary E. Ball, of Covington, Ky., whose death occurred in 1880.



LEWIS SAMUEL McMURTRY

Dr. McMurtry was the author of numerous contributions to medical publications on his specialties, gynecology and abdominal surgery. He was known to his many friends and to his colleagues as a man of unusual charm of personality and integrity of character as well as a surgeon of exceptional skill.

SIR ARCHIBALD REID, M.R.C.S., L.R.C.P.

London, England

Sir Archibald Douglas Reid, R.B.E., C.M.G., well known as a radiologist, died on January 15th at Chur, Switzerland, aged fifty-two. He passed his medical student's career at King's College Hospital, London, qualifying as M.R.C.S., L.R.C.P., in 1901, and specialized in x ray work, paying the penalty for his devotion in impaired health. In 1920 he took the diploma in medical radiology and electrology at Cambridge. During the war he rendered valuable service as president of the War Office X Ray Committee, and was created C.M.G. in 1917 and R.B.E. in 1919. In 1911-12 he was president of the Electrotherapeutic Section of the Royal Society of Medicine. At the time of his death he was superintendent of the radiological department of St. Thomas's Hospital and he was at different times radiologist of the Westminster Ophthalmic Hospital and the Evelina and Paddington Green Hospitals for Children, medical officer in charge of the electrical department of King's College Hospital, and consulting radiologist of the Queen Alexandra Military Hospital, Millbank, the Royal National Hospital for Consumption, Ventnor, and the Cray Valley Hospital. In 1920-21 he was president of the Society of Radiologists and he was also joint secretary of the Radiology Section of the International Congress of Medicine, and honorary member of the American Röntgen Ray Society.

Sir Archibald was the editor of *Localization and Extraction of Projectiles,* and he also made various contributions on his special subject to professional treatises and journals. His paper, which opened the Bilingual Congress of Radiology and Physiotherapy, was published in 1922 in the *Archives of Radiology and Electrotherapy.*

CHARLES E. WUEST, M.D.,

Brooklyn, N. Y.

Dr. Charles E. Wuest, assistant medical examiner in charge of Kings County, died on January 28th at his home in Brooklyn. He was in his sixty-first year. Dr. Wuest attained, perhaps, his greatest fame as an expert on autopsies, and was one of the foremost in this country. Born in New York City, he was graduated from the College of Physicians and Surgeons in 1888. He conducted a successful private practice until his appointment in 1898 as Kings County Coroner. Among other posts filled by him were those of pathologist at Bellevue Hospital, a position which he held for many years, of staff physician to the Wyckhoff Heights and to Saint Catherine's Hospitals, and of lecturer at Long

Island Medical College. Upon the abolition ten years ago of the office of Kings County Coroner, Dr. Wuest was made assistant medical examiner in charge of Kings County, a post which he filled with ability and honor.

His illness and death were very sudden. He was apparently in normal health upon arising in the morning, and a few hours later suffered a heart attack from which he never rallied. He is survived by his widow, two children, and a brother.

News Items.

Homeopathy Convention.—The American Institute of Homeopathy announces its eightieth annual convention to be held on June 22 to 27, 1924, at Cleveland, Ohio.

Change of Name.—The *North American Journal of Homeopathy* will be known in future as *The Pan-Therapist* and will be published at 546 Surf Street, Chicago, Ill.

Dr. Salamonowicz and Wife Here.—Dr. Arthur A. Salamonowicz, a leading surgeon of Russia and first medical consultant of the Russian army during the war, arrived in New York with his wife, Madame Helene de Netchajeva, operatic star, who is to make a concert tour of America.

Dr. Brown Radiographic Director at St. Luke's.—Dr. Percy Brown will replace Dr. Leon T. LeWald, who resigned as director of the radiographic department at St. Luke's Hospital. Dr. Brown is past president and recently Caldwell lecturer of the American Röntgen Ray Society.

Western Electrotherapeutic Association Meeting.—The sixth annual meeting of the Western Electrotherapeutic Association will be held in Kansas City, Mo., Thursday and Friday, April 17th and 18th, under the presidency of Dr. Harry H. Bowing, of Rochester, Minn.

Dr. Emerson Returns From Germany.—Dr. Haven Emerson, professor of public health administration at Columbia University, has just returned from a trip to Germany, made upon the request of General Allen's committee for the relief of German children.

Dr. Smithies to Give Third Bedford Lecture.—The third Bedford lecture of the Pittsburgh College of Physicians will be given April 24, 1924, at Pittsburgh, by Dr. Frank Smithies, professor of medicine at the University of Illinois, Chicago, on The origin and development of ethics in medicine and their influence on medical practice.

Yale Medical School Survey.—The Department of Public Health of the Yale School of Medicine is now making a study of health administration in communities of ten to thirty thousand population, in an effort to determine what health machinery in the way of personnel and money is needed in communities of this size for an adequate public health program.

Whiskey Standards in New Pharmacopœia. — Announcement has been made by E. Fullerton Cook, chairman of the revision committee of the United States Pharmacopœia, that standards for whiskey and brandy as medicines will be included in the pharmacopœia now being revised. This is in response to a demand by the physicians of the country.

Summer Sessions in Public Health. — The United States Public Health Service announces a summer session in public health at Columbia University, the University of California, the University of Michigan, and the University of Iowa. The faculties include Dr. Michael M. Davies, Dr. Robert H. Gault, Dr. Emery Hayhurst, Dr. William H. Park, Dr. Earl B. Phelps, Dr. George C. Whipple, and others.

March Post-Graduate Lecture Schedule.—The following Friday afternoon lectures will be given at 5 o'clock at the New York Post-Graduate Medical School and Hospital during the month of March: March 7th, The most important prophylactic measures in diseases of women, by Dr. James N. West; March 14th, The limitations of bronchoscopy and esophagoscopy (with lantern slides), by Dr. Charles J. Imperatori; March 21st, The management of typical fractures, by Dr. John J. Moorhead, and March 28th, Multiple neuritis, by Dr. John J. MacPhee.

Appropriations for Medicine.—Appropriations amounting to $10,500,000 have been made to continue fellowships in physics, chemistry, medicine, and the biological sciences in the United States under the auspices of the National Research Council.

The University of Pennsylvania has received offers of two gifts aggregating half a million dollars—$250,000 each from the Rockefeller Foundation and the General Education Board—on condition that it raise a like amount. The offer was accepted.

Experimental Phonetics.—During the summer semester, April 15 to July 15, 1924, six places in the Laboratory for Experimental Phonetics will be open to non-Austrians in the University of Vienna for the purpose of research. Further information can be obtained by letter to E. W. Scripture, Ph.D., M. D., Professor of Experimental Phonetics in the University of Vienna.

Andrew Todd McClintock Memorial—Mrs. Andrew Todd McClintock, widow of Dr. McClintock, of Wilkes-Barre, Pa., has created a trust fund of her estate, amounting to approximately $500,000, to be known as the Andrew Todd McClintock Memorial, to be used to conduct researches into the nature, causes and treatment of gastrointestinal troubles.

Cancer Congress Held at Brussels.—The International Congress for the Prevention of Cancer, held at Brussels, was attended by Queen Elizabeth of Roumania, British and French Ambassadors, Sir Claude Hill and many medical celebrities. Professor Hartmann, vice-president of the Franco-Anglo-American League Against Cancer, and Frederick L. Hoffman, of New York, were among the speakers.

Medical Women Receive Honors.—Dr. Esther Lovejoy, chairman of the American Women's Hospitals and President of the Medical Women's International Association, has been decorated with the Cross of the Legion of Honor at the French Consulate, for service to France during and after the war.

Dr. Florence E. Kraker, of Philadelphia, who has just returned from China, has been appointed specialist in maternal hygiene in the Children's Bureau of the U. S. Department of Labor.

Child Welfare Board Appointments.—Dr. Benjamin Schwartz, first assistant medical examiner of New York City and visiting physician to Gouverneur Hospital, has been appointed consulting physician and director of the medical service of the Board of Child Welfare of New York City; Dr. Charles Gordon Heyd, professor of surgery at the Post-Graduate Hospital, has been appointed consulting surgeon, and Dr. George Schwartz, instructor in operative surgery at the Post-Graduate Medical School and Hospital and attending surgeon of the People's Hospital, has been promoted from attending to visiting surgeon.

Hospital Building Additions.—The Infantorium now situated in the Heckscher Foundation, Fifth Avenue and 104th Street, New York, has increased its capacity to fifty beds. The following physicians are members of the attending or consulting staff and have given their services during the past year: Dr. Louis Fischer, Dr. John A. Fordyce, Dr. Isidore Friesner, Dr. George McAuliffe, Dr. H. S. Baketel, Dr. Charles Gottlieb, Dr. William H. Stewart, and Dr. Samuel S. Burk.

A new nine story patients' pavilion of Roosevelt Hospital has been formally opened which will increase the capacity of the hospital by about one hundred beds. The entire new pavilion, including equipment, cost $1,500,000.

Personals.—Dr. Arthur I. Blau has been elected secretary of the new Central Medical Club in New York. Meetings will be held on the first Friday in each month.

Dr. Louis Tulipan has been appointed consulting dermatologist to the Child Welfare Board of New York City by Acting Mayor Murray Hulbert, and Commissioner of Health Dr. Monaghan.

Dr. C. S. Bluemel has been appointed editor of *Colorado Medicine*, beginning January 1, 1924.

Mme. Curie was honored by the French Government on the event of the twenty-fifth anniversary of the discovery of radium, at the Sorbonne. Rector Appell of the Academy of Paris, Professor Perrin of the Sorbonne, Dr. Declere of the Academy of Medicine and Leon Bérard, Minister of Public Instruction, made addresses. A second ceremony was the inauguration of the Curie Foundation and was presided over by Paul Strauss, Minister of Hygiene.

Foreign Correspondence.

LONDON LETTER

(From our own correspondent)

London, *January 5, 1924.*

CHRISTIAN SCIENCE AND THE ENGLISH CHURCH

Following upon the Lambeth Conference of 1920, at which the challenge of Christian Science was discussed, the Archbishop of Canterbury appointed a committee of clergymen and laymen to consider the matter and report. After nearly three years of consideration the committee has now reached definite conclusions, which are embodied in a report presented to the Archbishop and to be published shortly. The encyclical of the Lambeth Conference stated that members of the Church "ought to take more account of the recent growth of knowledge about the power of the spirit over mind and body," and declared there was much in Christian Science which ought to be found within the Church, where it would be supplemented by truths which are neglected in Christian Science. The Bishop of Oxford was appointed chairman of the committee, whose members included the Bishops of Southwark, St. Albans and Liverpool, and a number of eminent physicians, among them Sir Clifford Allbutt, Sir Robert Armstrong-Jones, Dr. William Brown, Dr. W. H. Rivers and Dr. Jane Walker. Evidence was heard regarding healing by faith, the laying on of hands, and the blessing of the sick, and the committee considered the relation of these to the work and practice of the Church. It is understood that although the report welcomes the recent development of spiritual healing, it will not satisfy the more ardent advocates of it. It declares definitely that "no sick person must look to the clergyman to do what it is the physician's or surgeon's duty to do."

PRESENTATION TO PROFESSOR ALEXIS THOMSON

Dr. Alexis Thomson has been professor of surgery at Edinburgh University for many years. On account of ill health he has been compelled to give up the active duties of his post. A few days ago an interesting ceremony took place in the Surgery Lecture Theatre of the University of Edinburgh, when Professor Thomson was presented with a handsome silver model of an antique bowl as a mark of affection on the part of his former students.

THE MIDDLEAGED A NATIONAL ASSET

A short time ago Mr. J. S. Alford, in his presidential address to the Institute of Sanitary Engineers, said that "a continuance of a decline in the death rate is both undesirable and unlikely." This expression of opinion has not been allowed to pass unchallenged by the Ministry of Health. Longer lives are not a burden to the nation, said a Ministry of Health official to a press representative the other day. According to his view, the march of hygienic development has resulted in a race of men over fifty who are more efficient and of more general value to the nation than the average man of fifty twenty or thirty years ago. Mr. Alford at the same time stated that the more intelligent classes appeared to be diminishing relatively to the less intelligent. The retort of the Ministry of Health to this is that there has never been a higher level of intelligence in Great Britain than at the present time. Sir George Newman's report on the further saving of infant lives was quoted in support of the argument that the figures implied a better physical and a more enlightened understanding of personal and public hygiene which must contribute to the well being of men of over fifty and sixty years of age. It is contended that instead of being a burden to the nation men reared under the present conditions of scientific instruction are a great asset to the nation when they come to middle age.

FUTURE OF LEEDS GENERAL INFIRMARY

Leeds General Infirmary has gained more than a national reputation for both surgery and medicine and naturally the inhabitants of Leeds, and indeed of Yorkshire, take pride in the institution and of the surgeons and physicians who work therein. As is the case with the voluntary hospitals in all parts of Great Britain, the general infirmary at Leeds has fallen on evil times and at the present time its financial situation is precarious. In order to arouse the interest of business and professional men in the question, a meeting was held on December 17th last. Among the schemes set afoot the collieries in Yorkshire are to contribute on the basis of one farthing a ton of coal raised, and the miners one penny a week each. These together are calculated to realize £15,000 a year. By other organizations of the business centre of the city it is hoped to raise £2,000 a year. All this and much more will be needed as it is computed that the deficit on this year's working of the General Infirmary will be between £25,000 and £30,000. At the General Infirmary there is a list of twelve hundred to sixteen hundred people awaiting admission for operations and to open a new ward would cost four or five thousand pounds a year. Today the cost of maintaining the infirmary is £100,000.

NEW YEAR'S HONORS FOR MEDICAL MEN

The list of New Year Honors includes the names of fourteen members of the medical profession. Sir Donald MacAlister, principal of Glasgow University and president of the General Medical Council, becomes a baronet. Knighthoods have been conferred upon Dr. Henry William Russell Bencraft, of Southampton, and Dr. Byrom Bramwell, of Edinburgh, great as a physician and teacher. The Military Order of Knighthood of the Bath has been conferred on Lieutenant General Sir William Boog Leishman, Director General of the Army Medical Service.

LATIN AMERICA LETTER

(From our own correspondent)

Balboa Heights, C. Z., *January 10, 1924.*

MALARIA ON THE CANAL ZONE

The Governor of the Panama Canal, in his annual report for the fiscal year 1923, gives very interesting data relative to the occurrence of malaria. He states that "The total number of malaria cases reported from the Canal Zone and terminal cities during the year compared with the two previous years is as follows:

	1921	1922	1923
Employees	325	176	216
Military and Naval Personnel	810	828	870
Nonemployees	459	243	657
Total	1,594	1,247	1,743

The increase in the number of cases of malaria among nonemployees this year was expected and predicted as a result of the new policy of allowing unemployed laborers to return to the zone to take up land for agricultural purposes. It is impracticable to sanitate completely the country in which these settlers live. They are widely scattered over the available parts of the zone, living in rude shacks near water courses and the lake, and are at all times exposed to malarial infection. About 1,805 licenses have been granted these settlers and it is estimated that 650 families are now living on the land. Each home has a pit privy, not covered nor water tight, but at least limiting the chances of intestinal infection. Many have learned to boil their drinking water, and some are undertaking drainage. Aside from malarial infection, the venture seems surprisingly successful in most instances. Ground has been cleared rapidly and already many of the settlers have achieved what appears to be economic independence, at least according to their standards; are rearing their families in contentment; and are perhaps in better circumstances than similar agriculturists in Panaman territory. They have a certain amount of supervision by the American authorities, including the sanitation and police forces, and have, at least until they are able to pay for it, free medical service at the Panama Canal dispensaries and hospitals. In spite of the physical risk of living in practically unsanitated areas, and the present resulting increase of malaria in some of our sanitated areas, the net result of opening up the zone to land settlers is a great gain to the community in increased and cheaper food supply, and in converting a large number of idle pauper blacks, former Canal employees, into selfsupporting and selfrespecting individuals. The large reservoir of available labor supply so established may also prove of supreme importance to the Canal in time of sudden emergency. No licenses are granted within a mile of army posts and important residential sections of the zone, but unfortunately laborers residing in zone towns exchange visits with these settlers, and it is believed that many cases of malaria among the colored employees and their families have resulted from this practice."

ANTISTEGOMYIA CAMPAIGN IN CARTAGENA

Dr. Henry Hanson, Director General of the Sanitary Campaign Against Yellow Fever in the Republic of Colombia, reports that the antistegomyia campaign in Cartagena is making considerable progress. Sanitary Inspector J. B.Corrigan and Sanitary Engineer G. W. Stuart have been making studies with a view of converting a fish similar to Gambusia affinis from a salt water fish to a fresh water fish. The citizens of Cartagena and the newspapers thereof are cooperating heartily, and it is believed that the city will soon possess a safe mosquito index.

HONDURAS OPENS CENTRAL PUBLIC HEALTH OFFICES AND LABORATORIES

Largely through the efforts of Dr. Agustin Santiago Brizio, the Director General of the Public Health of the Republic of Honduras, Central America, there has been erected at Tegucigalpa a well equipped building containing the offices and central laboratories of the National Health Department. The ceremonies attendant upon the opening will be participated in by provincial and local health officers of Honduras and several other Central American republics. The buildings were to have been dedicated on January 20, 1924, but it has been necessary to postpone the ceremony until a later date.

VISIT OF DISTINGUISHED SANITARIAN

Assistant Surgeon General John D. Long, United States Public Health Service, arrived at Balboa, Canal Zone, on January 7, 1924, en route from Valparaiso to New York, in company with Judge Payne and Colonel Furber of the American National Red Cross. Dr. Long, who has been in attendance at the Pan-American Red Cross Conference at Buenos Aires, was entertained by the Chief Quarantine Officer of the Panama Canal and spent the day in visiting the various sanitary works of the Panama Canal. He sailed for New York on the *Santa Luisa* on the evening of the same day, after discussing the plans for the Conference of Maritime Quarantine Authorities of South American Pacific Ports with President Belisario Porras, the Honorable Dr. Narciso Garay, Secretary of Foreign Affairs, Colonel H. C. Fisher, Medical Corps, United States Army, the Chief Health Officer of the Panama Canal, and Surgeon W. C. Rucker, United States Public Health Service, the Chief Quarantine Officer of the Panama Canal and Secretary General of the Conference.

TUBERCULOSIS SANATORIUM FOR PANAMA

President Belisario Porras and a distinguished official party including Dr. A. S. Boyd, the chief surgeon of Santo Tomas Hospital, have gone to the Valley of the Anton in the interior of the Republic for the purpose of selecting a site for a tuberculosis sanatorium. The altitude at this point is about two thousand feet and the climate is believed to be well suited to the open air treatment of tuberculosis. If the sanatorium is located there, it is planned to connect it with the national roads so that communication with the rest of the Republic will be rendered easy. The Republic is making a strenuous effort to induce the American government to construct a bridge across the Canal and if this is done it will be easy on the completion of the road for an automobile to make the journey from the capital in about two hours.

CHILD HEALTH ASSOCIATION TO STUDY CANAL ZONE CHILDREN

Miss Sally Lucas Jean, directress of the Child Health Association of America, will arrive on the Isthmus in early January accompanied by Miss Emma Dolfinger for the purpose of making an intensive health study of the Canal Zone children. The survey will take about a month and it is expected that Miss Jean will make a report of her findings with suitable recommendations. Present notices state that in the Balboa District of 748 children, 428, or 57.2 per cent., were found to be defective in some way. Of the 428, 54 had faulty vision, 178 defective teeth, 12 defective audition and 116 some nose and throat condition. Two hundred and thirty-three had dental defects of one sort or another. None of these cases were in any way serious but it is desired to discover them in the earliest stages in order that they may receive prompt and efficient treatment.

MEDICAL TREATMENT BY AEROPLANE

Army aeroplanes from France Field which have been making extensive flights into the interior of

Panama have recently completed a successful round trip flight to San Jose, Costa Rica. On one occasion after receiving a telegram to the effect that the wife of an explorer in Chiriqui had been wounded, planes proceeded to the camp where she was, taking with them a physician and a supply of antitetanic serum. After the administration of the serum the lady was brought to the Ancon Hospital for treatment. Had she traveled by boat it would have taken at least three days for her to reach Ancon. Recently a plane flew from David to France Field with a horse weighing six hundred pounds and it is felt that it has been amply demonstrated that by using aeroplanes it will be possible to transport with great ease and rapidity urgent cases from the interior to the hospitals at the capital.

INCREASE IN CANAL TRAFFIC

During the calendar year 1923 more than five thousand ships made the transit of the Panama Canal and paid tolls in excess of $23,000,000. In spite of the fact that these vessels came from all over the world no cases of quarantinable disease have been introduced into the Canal Zone during the year and by reason of the improved methods in quarantine, time losses in ships have reached what is practically an irreducible minimum. With this increased traffic the medical and surgical work of the United States Public Health Service on the Canal Zone has increased very materially. During the year 867 cases were treated in hospitals and 371 in dispensaries, the cost of such treatment amounting to $27,932.

PANAMA CANAL GROWS CHAULMOOGRA TREES

The Health Department of the Canal Zone is now growing chaulmoogra trees and it is hoped that within the next five years the local supply will be sufficient to treat all lepers on the Isthmus. These trees were introduced into the Canal Zone in 1921 when about a dozen young plants were planted at Corozal and Mount Hope. The first yield is expected this year and is being eagerly watched by health officials of the Zone. The tree is not unlike the mahogany in appearance. It is tall and straight, often growing to ten or fifteen feet in height. Its smooth bark has a pale yellowish brown tinge but the branches appear low down and grow at right angles to the tree. The leaf is long, slender and ribbed like the mango or mahogany and the fruit is brown and russet colored and about the size of a large orange. The seeds in this fruit are arranged like those in the pomegranate but are somewhat larger.

HOOKWORM CONTROL IN PANAMA

Dr. Louis Schapiro, addressing the Isthmian Canal Medical Association recently, said that the campaign for the control of the disease is conducted by the Department of Uncinariasis, an official agency of the Panaman Government, in the Ministry of Fomento. Dr. Schapiro, who is the local representative of the International Health Board of the Rockefeller Foundation, cooperates with the Government in order to establish the work on a permanent basis. There are central offices in Panama City with a laboratory for the examination of fecal specimens. There is a field staff of sanitary inspectors and an adequate personnel of laboratory workers, technical assistants and microscopists. A technical assistant, a sanitary inspector and one or more microscopists constitute the unit of operation. The campaign has been hampered by transportation difficulties and has passed a transition type. At first the work was conducted on the dispensary plan. This consisted of an ambulatory unit comprised of a technical assistant and several microscopists. The unit operated for a short time in each area and offered examination and treatment to those infected. The method was soon found to be ineffective because the patients were permitted to take the medicines home with them to selfadminister them if they saw fit. This was changed so that now the drugs are taken in the presence of the technical assistant. The present plan is to select a geographic or political area, map it and make a complete sanitary census after which a public conference is held and privy construction commenced. When seventy-five per cent. of the homes are provided with privies a laboratory census is made. After ten per cent. of the population has been examined, if the infection rate exceeds eighty per cent., treatment is offered to all inhabitants without previous or further examinations. This is the socalled mass treatment. It has been found sound; it certainly reduces the cost of the campaign and eliminates time wastages. All treatments are given in the laboratory, three treatments of chenopodium being administered at ten day intervals. Coincident with the examinations and treatments an educational campaign is carried on.

Up to and including 1922, more than 140,000 persons were examined and an infection rate of 80.4 per cent. was found. Of this group 104,000 received one or more treatment and 78,000 were discharged after two treatments. The infection rate according to race groups shows: Whites, sixty-four per cent.; brown or moreno, ninety-one per cent.; negro, ninety-eight per cent.; and yellow, forty-three per cent. No marked difference in the infection rate according to age groups was found. In the school children of Panama City and Colon the infection was 11.3 per cent. as against 99.2 per cent. in the rural districts.

MOSQUITO PREVENTION PLANT MAY BE NUISANCE

The division of sanitation, of which Dr. D. P. Curry is the chief, has naturally been much interested in the reports of the use of *Chara foetida*, a water plant, in the prevention of mosquito breeding. This particular species is not present on the Isthmus but investigation shows that *Chara foliarosa* is prolific in the shallow lakes bordering the Canal. Apparently this species exerts no inhibitory effect on mosquito breeding. It grows in all shallow lake areas and has proved so troublesome that the municipal engineering division of the Panama Canal has been obliged to remove it by the expensive and tedious process of dragging it out by boats. The plant grows especially fast in the dry season when the water is clearer, shallower and there is more sunshine. It has spread rapidly in the past four or five years and the work of removal must be done almost continuously. Its presence interferes with the use of oil or other larvicides and apparently the anopheles delight to breed in the shallow pools in which it grows, sending up tendrils which mat at the surface of the water to such an extent that larvæ destroying fish cannot penetrate the blanket thus formed. In view of these facts it is believed that *Chara* should not be introduced as a mosquito control measure without further investigation since it is of doubtful value and may grow to an extent which will make it a nuisance.

Book Reviews

GASTROINTESTINAL SURGERY

Indikationstellung für die chirugische Behandlung bei bäsiertigen und gutartigen Erkrankungen des Magens and Duodenum. By Prof. Haberer. Halle: Carl Marhold Verlagsbuchhandlung, 1923.

Haberer prefers the resection of ulcers to gastroenterostomy. Duodenal ulcers in the descending portion of the duodenum, however, especially if adherent to the gallbladder or penetrating the pancreas, do not permit resection and require a gastroenterostomy. Haberer sees no good results from operations for gastroptosis and considers them useless. In callous ulcers the resection is absolutely necessary for in a great number of them the apparently benign ulcer on microscopic examination proves to be already cancerous.

The monograph gives a full description of the author's very rich experience in gastrointestinal surgery.

COSMETIC SURGERY

Die Behandlung der kosmetischen Hautleiden unter besonderer Berücksichtigung der physikalischen Heilmethoden und der narbenlosen Operationsmethoden. Von Professor Dr. E. Kromayer, Berlin. Mit 7 Abbildungen. Leipzig: Verlag von Georg Thieme, 1923.

This brochure contains the author's observations, investigations and experiences in the field of cosmetic treatment of the skin during a period of thirty years. The material is arranged so as to show the results in the various skin diseases with the method of treatment especially indicated, such as röntgenotherapy, radium, light, the technic of operating without the leaving of scars, cauterization, electrolysis, heat, cold and the local applications of drugs. This work is concerned, particularly, with the methods of removing blemishes of the skin cosmetically—without resulting unsightly scars. The latter element of the result is generally not taken into consideration, but certainly deserves to be considered, especially in the patient who is distressed by skin blemishes and is determined to have them removed.

HISTOLOGY

Practical Morbid Histology. Robert Donaldson, M.A., M.D., Ch.N. (Ed.), F.R.C.S.E., D.P.H. With foreword by Sir Humphrey Rolleston, K.C.B., M.D. London: William Heinemann, Ltd., 1923.

The purpose of this book is to present in a concise form the essentials of pathological morphology as they are viewed by the student who desires to get and retain a working knowledge of the more obvious changes caused by disease. The close association in the text of the gross and microscopic pictures is a convenience in teaching, but also limits the scope of both phases of the subject. To divorce the clinical aspects of the case from the postmortem findings seems to remove pathology an unnecessary distance from its place in the practice of medicine, and to inhibit, rather than to stimulate, the students' critical faculties. The book may be useful as a students' manual, however, and could be used in connection with lectures which would greatly amplify and illustrate the text. The language is somewhat colloquial, but entirely clear, and the descriptions so brief as occasionally to do scant justice to the facts, for example, in the description of hemochromatosis and other rare diseases. On the other hand, the material on industrial diseases, e. g., of the lungs, is presented in a concise and interesting manner, and makes available facts which are not fully dealt with in many larger texts. Even to the elementary student the absence of illustrations and of a bibliography might prove a keenly felt defect.

ANATOMY

Quain's Elements of Anatomy. Eleventh Edition. Vol. IV. Part II. Myology. By T. H. Bryce, M.A., M.D., F.R.S. New York and London: Longmans, Green & Co., 1923.

From all intents, this is a new book rather than a new edition. This work will be heralded by many as a contribution to the new school of dynamic medicine. The book is replete with the excellent illustrations which characterized the earlier editions, but most important is the concept of the muscular organism as an entire unit. Morphological descriptions are skilfully united with genetic concepts. A long needed work on anatomy. May its reception be in keeping with its quality.

SHIP SANITATION AND HYGIENE

Manual on Ship Sanitation and First Aid for Merchant Seamen. By Robert W. Hart, Passed Assistant Surgeon, United States Public Health Service. Second Edition. New York: Seamen's Church Institute, 1923.

The second edition of this useful and practical little book contains important revisions of the original text and considerable added material. The aim of the manual is to supply a basis for a more intelligent relationship between masters and men of the Merchant Marine and the Public Health Service, which is the Federal agency charged with definite responsibilities in matters affecting their health and the quarantine of vessels operated by them. Dr. H. S. Cumming, Surgeon General of the Public Health Service, states in a foreword to the volume that "the promotion of a spirit of mutual trust and good will between the American Merchant Marine and the Public Health Service is a matter of vital importance which concerns the entire nation."

The manual is designed to furnish to officers and men of the Merchant Marine a small but comprehensive text book on general ship sanitation and hygiene, and an outline of the common medical and surgical conditions that obtain on shipboard, together with directions for the treatment of diseases and also for the proper care of injuries. There are chapters on anatomy and physiology, the ship's sick bay and medicine chest, medical first aid, surgical first aid, etc. An attempt has been made to include also some practical information on bedside nursing, the use of simple remedies, and instructions enabling the layman to cope with conditions sometimes following serious accidents at sea.

The language is simple and the terms used as nontechnical as possible. Cuts and drawings illustrate the text.

TUBERCULOSIS

Pulmonary Tuberculosis. By JOHN GUY, M.D., D.P.H. (Camb.), F.R.F.P. & S. (Glas.), F.R.C.P (Edin.). OLIVER & BOYD, Edinburgh, 1923; 307 pages.

In the introductory chapter of this textbook the author gives a short historical survey of tuberculosis science from the time of Hippocrates to the present day, and justly gives to Bodington, an Englishman, the priority as a pioneer of the open air treatment. In chapter 2, besides the statistical charts of England and Wales, he gives interesting data on the comparative deathrate in Scotland for the year 1921, according to which it is in the rural districts 68 per 100,000 inhabitants, in small burghs 70, in large burghs 95 per 100,000.

In the description of the tubercle bacillus, nothing new is given, but an excellent picture in color is reproduced. In the chapter on pathology the author describes carefully the four well known methods of the spread of tuberculosis in the lungs: 1, by discharging into a bronchus (aerogenous); 2, by contiguity, that is, gradually spreading into the neighboring tissues; 3, by the lymph stream (lymphogenous); 4, by the blood circulation (hematogenous). The statement is interesting, coming from an Englishman, that forty per cent. of the milch cows in Great Britain are infected with tuberculosis, and he pertinently says that the prevention of distribution of the tubercle bacillus is to be secured by the control of the consumptive patient and the tuberculous cow.

In the chapter on predisposition, the author reproduces the interesting table on comparative mortality in certain occupations, compiled by Collins, which gives the astounding figures that the tin miner is eight times, the cutter five times, the printer three times, the shoemaker and tailor two and one half times, the hosiery operator two times more exposed to contracting tuberculosis than the coal miner or agriculturist. The author gives the well known list of predisposing diseases and tries to explain the frequency of the lesion in the apex by a stenosis of the upper thoracic aperture, which in turn causes lessened respiratory effort, diminished blood supply, and a comparative lymph stasis.

The physical examination of the patient is treated thoroughly in this book and an unusually large number of excellent photographs of patients stripped to the waist illustrate the value of careful inspection and method of palpation. Under special tests, the author describes the sputum albumen reaction, the exercise or autoinoculation test, the opsonic index test, and the various tuberculin tests. It is surprising that the author should have devoted nearly ten pages to the description of these various tests the majority of which he himself admits to be unreliable. Albumen is found in the sputum of patients suffering with bronchiectasis or abscesses of the lung, and in the early stage of tuberculosis albumen is rarely found in the sputum. That the autoinoculation test is unreliable one can see if he thinks of the many factors which may cause a rise or an irregularity of temperature even in a healthy person. The opsonic index test is equally unreliable because of its many chances of error, and the complement fixation test is difficult because of the procuring of a suitable antigen. Dr. Guy favors the intradermal test of Mantoux and von Pirquet, but with all modern investigators he admits that the reaction means an infection and nothing more.

Some very excellent x ray pictures complete the chapter on diagnosis. The symptoms for differential diagnosis, such as are observed in bronchitis, asthma, bronchiectasis, empyema, abscesses, gangrene, neoplasms, and mitral stenosis, are carefully described, and so are the frequent complications of pulmonary tuberculosis.

Under tuberculin therapy the author confesses that, according to his own experiences, the value of tuberculin as a remedial agent is "not proven." Under symptomatic treatment, nothing new is offered, but it is rather surprising to see the number of drugs mentioned in the treatment of hemoptysis which, as is well known, are, with the exception of morphine of no use. In his chapter on artificial pneumothorax, the author very wisely recommends that when large quantities of gas are not tolerated well, smaller quantities of about three hundred c. c. may be injected every two or three days until a total collapse is obtained. When this is reached, a positive pressure of five to ten c. c. is sufficient to maintain it. In the author's description of climatic treatment, he expresses himself rather favorably on marine climates as particularly suited for emphysematous patients and those with chronic bronchitis. This is a rather surprising statement, for chronic bronchitis usually does a great deal better in high and dry climates.

The last chapter is devoted to sanatorium treatment in institutions and at home. Dr. Guy wisely refrains from discussing the comparative merits of the treatment at home or in a sanatorium and well says that the two are complementary, because as proved by statistics, the majority of patients must be treated at home, the home treatment should be considered as most important in the tuberculosis problem. Aside of the few slight criticisms, the book is well written and well printed and constitutes a good handbook for students and general practitioners, which is all the talented author claims for his work.

THE UNCONSCIOUS

The Unconscious. By ISRAEL LEVINE, M.A. New York: The Macmillian Co., 1924.

A sketchy survey of the unconscious, historical and from the time of Freud. The workers previous to Freud are dismissed a bit casually perhaps for fear that the master will not receive adequate due. There scarce seems need for this. The résumé of the work done by Freud and the psychoanalytic school is fairly well done. As to the advisability of classing this book as a general introduction to psychoanalysis, there is grave doubt. Freud has written a fairly good "general introduction" and this book does not in any way supplant it. Just what function Levine's book fulfills is difficult to state. It is made up from a series of quotations selected from various workers in the psychoanalytic field and why Levine's judgment should be any better than that of any other reader is somewhat vague.

There are no short cuts to so important a subject. It seems of far more value at present to contribute something than rehash a subject during its period of adolescence. However, there are certain types of mind that must have an outlet. The college professor insists on going through the literature and selecting what he thinks best. So be it.

THE NARRATIVE OF A WOMAN PHYSICIAN

Beginning Again at Ararat. By Mabel Evelyn Elliott, M.D. New York and Chicago: Fleming H. Revell Co., 1924.

The chronicle of a modern Florence Nightingale is perhaps the best way to characterize this remarkable human document. For four years Dr. Elliott has been one of the prominent members of the American Women's Hospital's personnel in the Near East. This book is her account of those years of life amid almost unspeakable horrors and of the methods of relief undertaken by herself and the other Americans working with her. Of them she writes, "Every American who went to the Caucasus was a hero. Of myself I do not speak . . ."

Dr. Elliott's experiences in the Near East, as recounted in her book, were divided into three distinct periods. First, she tells the story of her hospital at Marash in Central Anatolia, and of the medical relief work done there for the population during occupation by the French army, of the long siege by the Turks, of the midwinter evacuation, and subsequent march through cold and snow, without provisions, on which she accompanied the evacuated populace. Her next post was Ismid, near Constantinople, where she was instrumental in establishing a hospital with one hundred ward beds, a clinic and a nurses' training school. No sooner was the organization in good running order than the Greek ococupation yielded to the Turkish, whereupon the hospital sent away almost all its nurses with the evacuation, but Dr. Elliott remained and kept the institution open several months longer under Turkish rule of the city. Her next work was in the Caucasus, where she organized and directed hospitals for the Armenian refugee children. Her record closes with the account of this tremendous task, during which she had to cope with the results of war on a vast scale. Dr. Grace N. Kimball, president of the Medical Women's National Association, tells us in a prefatory appreciation of the book, that Dr. Elliott, as many know, answered a later call to service and hurried back to Constantinople to do relief work following the Smyrna tragedy and the horrors of the evacuation of Anatolia.

The book is full of most interesting medical material. One of Dr. Elliott's posts was that of head of a home for Armenian girls released from Turkish harems. "The things I heard were unbelievable," she writes. "A doctor sees more deeply into the abysses of human society than any other person except a priest, but I knew only America. This was Asia, strange, bestial, incomprehensible. It was my first encounter with such things—the things that human beings can do, carelessly, without rancour, laughing, to other human beings. It was incredible, too, that these girls could have seen and endured them, and survived to sit there telling of them. The stories did not vary greatly; the variety was in the revealed temperament of the girls." One of the most vivid parts of the narrative is the diary of the siege of Marash, kept by the author, and the account of the three days' flight from the city through winter snows with five thousand Armenians, of whom perhaps one third lived to reach their destination. The marvel is how Dr. Elliott, under such circumstances, was able to keep any record at all of her experiences and splendid work. The accounts of the medical work with the Turkish women and in the orphanages in the Caucasus are equally interesting.

The book is simply, directly and forcefully written. On not a single page does the reader's interest lag. Perhaps the most striking characteristic of the narrative is that it is told with such a tremendous modesty. In it we see the spirit of one who has passed forever beyond the personal and is one with mankind as a whole. Courage, too, never fails her, either under the enemy's fire or in speaking her convictions. "The Turk is a barbarian," she writes. "In seven hundred years, he has learned nothing from the civilization of Christian Europe. But what are the lessons that Christian Europe has set him to learn?" The book contains many penetrating, practical and revealing political comments, as well as interesting and delightful descriptions of places and peoples.

TIGHTROPE PSYCHOLOGY

Outline of Psychology. By William McDougall. New York: Charles Scribner's Sons, 1923.

McDougall is a man of learning, a man in a most responsible position. He knows what is needed in the literature of psychology. He realizes how befuddled psychologists of the old school have been. He senses the sweeping on of the new virile school of psychology and has a wondrous knack of synthesizing his knowledge and presenting it in attractive form. From him we should expect a truly great book on psychology.

For these, and many other reasons, his present volume is a keen disappointment. Replete, it is with material most of which is good and then—confusion. Temporizing; definition upon definition without a clearcut one among them. Not one that is not as weak as near beer. Perhaps McDougall is apprehensive that the eighteenth amendment may apply to psychology. Granted that anything concise and clearcut is an anathema to the university psychologist, is it not a high price to pay for popularity to trim ones sails under these conditions? Alas, we fear we shall have to put this book among the many others which are handed "down" to the student of psychology. Others will come and soon. Yet we are disappointed when we had expected as much from McDougall. The opera singer with the glorious voice singing jazz for *hoi polloi.*

ROCKEFELLER INSTITUTE STUDIES

Studies from the Rockefeller Institute for Medical Research. Reprints. Volume XLVI: New York, The Rockefeller Institute for Medical Research, 1923.

This bulky collection of reprints represents the activities of the Rockefeller Institute for Medical Research during the past year. To those who have not followed the work as it appeared month by month in various publications, the present volume will be especially interesting. The reprints embrace studies on pathology and bacteriology, biophysics, chemistry, experimental surgery, general physiology, and animal pathology, and as an evidence of the extremely wide scope of the scientific investigations which are being carried on at the Rockefeller Institute for Medical Research.

Medicoliterary Notes.

Mental Health is the title of a leaflet which the Mental Hygiene Society of Maryland has recently begun to issue. The editor is Dr. Charles B. Thompson, consultant and executive secretary of the society. The purpose of this little publication is to furnish information to the lay reader and to the public at large on the principles underlying mental hygiene.

The former crown prince of Germany admits, in a letter to his former teacher, Professor Zorn, quoted in a recent issue of the *Living Age,* that "thinking has gradually become a habit" with him.

* * * *

The General Assembly of Pennsylvania, during its session of 1923 passed an act known as the Bedding and Upholstery Act, which provides for the inspection and tagging of all mattresses, pillows, bolsters, feather comfortables, cushions, and other articles of upholstery.

* * * *

A recent issue of the *New York Medical Week* praises the Joint Legislative Committee under Senator Cotillo's leadership for the real service it is performing in investigating the robbery of immigrants by various agencies. "The dishonest medical advertising in papers published in the foreign languages," says the editorial, "is the crux of this whole rotten system. . . . Only if this is eliminated can the situation be bettered. If the Cotillo investigation will result in effective legislation against such advertisements, it will indeed have accomplished a great part of its purpose."

* * * *

The Expert Witness is the title of a recent English publication, of which C. Ainsworth Mitchell is the author. It deals with the application of science and art to human identification, criminal investigation, etc. The author is an expert on handwriting, finger prints, and kinds of ink, and has besides the literary ability to make his book intensely interesting and at times thrilling.

* * * *

Carl Hookstadt, writing in a recent number of the *Monthly Labor Review* on the number and cost of industrial accidents in the United States, estimates that the annual cost of such accidents in this country is $1,023,104,435, plus at least $75,000,000 for medical and hospital service, to which should be added the administrative expenses of compensation commissions and insurance companies, and the indirect effect upon production.

* * * *

The Schoolmaster, an English magazine, publishes some amusing answers to examination questions. One girl wrote that the Roman numerals LXX stand for "love and kisses." Another, answering the question, What discovery was due to the falling of an apple? replied "the wickedness of Eve."

* * * *

The Detroit Public Library has opened a medical branch. The books forming the collection were formerly the property of the Wayne County Medical Society, which last winter requested the public library to take over the collection and house, organize and manage it for the future.

* * * *

Scientific men serving with the British forces in Mesopotamia have been able to study, collect and even preserve specimens of fauna, sometimes under fire, as is shown by a volume recently published by the Natural History Society of Bombay on the fauna or Iraq. The book reports that some of the specimens were captured close to the enemies' lines, and many were caught within artillery range. A colonel caught and skinned a shrew while under shell fire.

* * * *

The Chicago Health Department reports that, out of 56,724 births occurring in 1922, not a single case of blindness has developed. This, they state, was due to the physicians, midwives, hospitals, and the Illinois Society for the Prevention of Blindness, cooperating with the Board of Health.

A musical review states that there is only one man in the world who can read the scores of Puccini's operas, which are practically illegible. This man is employed by the publishers of Puccini's scores in Milan, who, it is reported, are using this fact to make it very uncomfortable for the great musician, who is engaged in a lawsuit with them.

* * * *

A method of disinfecting hides and skins with iodine for anthrax is described in detail in an article by Dr, Henry F. Smith and Edwin F. Pike, both of the University of Pennsylvania, in a recent number of the *American Journal of Hygiene.*

* * * *

The Gaol, a novel by Paul Bourget, soon to be published by Brentano, is a story of the influence of heredity, from which the hero is depicted as being unable to escape.

* * * *

Dr. Edward J. Kempf, in an interview published in a recent issue of the Sunday New York *Times,* is quoted as making a special plea for vocational schools as an aid in the care and treatment of the mentally diseased, of whom he considers eighty per cent. curable.

* * * *

The Real Sarah Bernhardt, by Mme. Pierre Berton, with illustrations from rare prints and photographs, is announced by Boni & Liveright for publication in February. It is said that this biography will reveal phases of the great actress' life and character known only to her intimates.

* * * *

The Department of Information and Statistics of the National Committee for Mental Hygiene is preparing a study on the use of alcohol in relation to mental disease. This article contains social facts concerning patients admitted to ninety-six hospitals in this country during the year 1922, and shows the decrease in this form of mental disease during recent years. It aims to correct some current fallacies concerning the effects of prohibition on mental disease. It will be published in the *American Review.*—*Mental Hygiene Bulletin.*

French colonists in tropical Africa are losing their fear of the tsetse fly, which transmits the germ of the sleeping sickness, and it is expected that in a few years the dangerous character of this insect will be a legend. The pest is being fought with a tropical plant, Melinitis multiflora, the pungent odor of which the fly is unable to stand. The peculiar qualities of this plant first came to the attention of the settlers through its use by the natives in the sleeping quarters of their fowls and domestic animals. Its odor is so strong that the natives are unable to stand it in large quantities, but it is said to be pleasing in small quantities. The plant grows riotously in various parts of the Ivory Coast Cameroon, Portuguese Congo, and Madagascar.—*Medical World.*

* * * *

The Claims of the Coming Generations, edited by Sir James Marchant, Secretary of the British National Birth Rate Commission, is one of Dutton's recent publications. The book is a collection of articles by authorities on the care and training of children. Among contributors are Dean Inge, of St. Paul's, London, who writes on the right to be well born; J. Arthur Thomson, who discusses sex education; Dr. Mary Scharlieb, whose subject is the moral training of the modern girl, and Sir Arthur Newsholme, who writes on improvement in child welfare.

In the book review section of the February 6th issue of the JOURNAL Richard G. Badger, of Boston, was credited with publishing *Der Fetischmus* by William Stekel. This is an error, the publishers being Urban & Schwarzenberg, of Berlin and Vienna.

* * * *

What is believed to be the first instance in England of an alliance between a general hospital and a special hospital for the care of mental disease is a scheme recently approved whereby the Middlesex Hospital has opened two new wards, for men and women respectively, for the treatment of functional disorders of the nervous system. . . . Both hospitals share funds, materials, and experiences and service of the staff as may be necessary. The resources of the general hospital in the nature of special examinations, medical and surgical treatment, and the like are available for the patients.—*British Medical Journal.*

Abstracts from Current Literature

GASTROENTEROLOGY

Duodenal Enzymes in Chronic Ulcerative Colitis.—Philip W. Brown (*Medical Clinics of North America,* July 1923) states that the enzymatic activity of the duodenal contents in cases of ulcerative colitis has been reported as high. In active cases this enzymatic activity is more marked, and, conversely, it is decreased as the condition subsides. There is evidence that a normal enzymatic activity may exist in the presence of chronic pancreatitis. It is important to note that the activity, not the amount of the enzymes, is estimated. Furthermore, the results should be expressed in the general terms of proteolytic or amyolytic activity, and not as due only to trypsin or amylopsin. One case of ulcerative colitis demonstrated that the enzymatic activity at the ileocecal valve is practically as powerful as it is in the duodenum. This explains the skin digestion in the patients with ileostomy, and may be the factor causing the ulceration, if a decreased resistive power in the colon wall is assumed.

Gastroduodenostomy versus Gastroenterostomy in the Treatment of Chronic Duodenal Ulcer.—E. R. Flint (*Lancet,* September 8, 1923) believes that gastroduodenostomy can be done in ninety per cent. or more of cases of duodenal ulcer, and that gastroenterostomy is necessary in less than ten per cent. of cases of chronic duodenal ulcer. The risk to the patient with gastroduodenostomy is no greater than it is with gastroenterostomy. The occurrence of an ulcer at the line of the anastomosis after gastroduodenostomy is unknown, whereas it does occur in at least two per cent. of cases after gastroenterostomy. In a small percentage of cases it is also impossible to do posterior gastroenterostomy, either because of a small stomach in a fat patient, or because the lesser sac, or that part of it which is required for the operation, is obliterated by adhesions. Anterior gastroenterostomy is then usually done, and this is not a desirable operation.

Etiology of Gastric and Duodenal Ulcer.—George E. Ebright (*California State Journal of Medicine,* October, 1923) believes that, in the light of the work of Rosenow and others, upon the possibility of the bacterial origin of gastric ulceration, it is of the utmost importance that infections, especially chronic focal infections, be borne in mind. While the teeth and tonsils and intestines rank first as offenders and should receive the most painstaking attention, it is necessary to remember the possibility of chronic processes in the accessory sinuses of the nose, the middle ear and mastoid, the uterine cervix and fallopian tubes, prostate, gallbladder, and appendix. He also believes that it is correct to consider two kinds of causes of gastric and duodenal ulceration, namely, exciting and predisposing, that predisposing factors are usually remote, such as constitutional diseases and focal infections; that exciting causes may be dietary indiscretions, acute infections, and psychic disturbances leading to the condition which is commonly recognized as nervous indigestion. Without emphasizing the latter unduly, it may be stated that alterations in the physiological functions of the stomach and duodenum due to nervous influences are a frequent cause of ulceration.

Cause of Death in Intestinal Obstruction.—As a result of his experimental work. Seton Pringle (*Lancet,* July 14, 1923) draws the following conclusions: 1. The principal factor in causing death in intestinal obstruction is a toxin which is developed chiefly in the duodenum, and, although it is not absorbed from the normal intestine, it is absorbed under the conditions which prevail in obstruction. 2. The exact chemical composition of the toxin is still under dispute, but it is almost certainly of the nature of one or other of the toxic bodies derived from protein disintegration. 3. The exact mode of production of the toxin is also undecided, but probably the presence of pancreatic secretion, and, in a lesser degree, the activities of bacteria are necessary for its production. 4. While the duodenum is the site of maximum toxicity in obstruction, yet the poisonous substances are developed lower down in the intestine, and it is probable that in the production of these toxins bacterial action plays an important rôle—a rôle which increases in importance the lower down the obstruction occurs.

The author believes that three factors are at work in acute peritonitis: 1, shock; 2, septic absorption from the peritoneum, and 3, toxemia from the intestine, the involved part of which is generally in a condition of paresis, producing obstruction. He has saved cases which were seemingly quite hopeless by not only using morphine and saline glucose infusions to combat the shock and toxemia, but also by attacking directly the source of the toxin by means of an enterostomy high up in the small intestine, after the manner of Witzel's gastrostomy. A No. 12 soft rubber catheter is inserted into the lumen of the intestine through a small puncture and fixed in position by a single catgut stitch, the next two inches are buried in the intestinal wall by a continuous infolding stitch, and the proximal end is passed through a hole in the omentum, as described by Mayo, before being brought out through the abdominal wall. To the end of the catheter a long tube is attached to drain into a bottle beside the bed.

Kymographic Studies of Various Pathological Conditions of the Stomach.—Leo L. J. Hardy and Edward G. Joseph (*Medical Clinics of North America,* July, 1923) compared and classified the changes in gastric motility and intragastric tension with the aid of the balloon and kymograph for the purpose of diagnosing pathological conditions. One hundred and twenty kymograms were classified into three characteristic groups: 1. The peristaltic waves may be diminished, as is also the tonus rhythm, in a large percentage of these patients having duodenal ulcers with positive röntgenograms. 2. The peristaltic waves may be more active and the tonus rhythm accentuated, and, in striking contrast to the group 1 cases, the greater number of these patients are either normal or have reflex gastric symptoms. 3. The peristaltic waves are greatly increased and the tonus may or may not be correspondingly intensified; this is a small group, too small from which to draw any conclusions. The few kymograms which showed diminished intragastric tension were found to belong to those patients who had been suffering from marked general debility and asthenia. The effect of the alkaline treatment for duodenal ulcer on gastric motility causes marked diminution of the various motor activities of the stomach, although intragastric tension remains within normal proportions. The action of belladonna produces effects similar to alkaline treatment. In regard to the factors concerned in the etiology of gastric pain, the results emphasize the view that peristalsis and increased intragastric tension are of primary importance in the causation of pain. The experiments with belladonna lead to the belief that there may be something besides peristalsis and an adequate acidity necessary to the production of pain. It is suggested that the afferent sensory mechanism may be inhibited independently of the peristalsis and tonus variation.

Some Etiological Factors in Appendicitis.—A. C. Guillaume (*Gazette des hôpitaux,* September 22, 1923) states that, when only cases in which the appendix shows lesions justifying the diagnosis of appendicitis are taken into account, the ratio of cases in males to cases in females is at least seven to three. In grouping cases according to severity of the appendix lesions, one finds severe lesions uncommon and mistakes frequent in women, whereas in men severe lesions obtain in a majority of the cases and only a few of the lesions are questionable. Lack of results from appendectomy and return of pain after the operation is far more frequent in women than in men. Among the patients unimproved by appendectomy there are many in whom colic and pericolic lesions have been observed at the operation and stasis disturbances after the operation; among these cases medical treatment yields a considerable proportion of cures or cases markedly improved. Careful examination of patients, particularly with the x rays, permits of the elimination of at least eight out of ten of the cases in which the diagnosis of chronic appendicitis is ordinarily made. Examination under fluoroscopic control shows that the points of tenderness attributed to the appendix are in reality located over the ascending colon; that the appendix is not tender and is movable and permeable, and that there are present intestinal and periintestinal lesions, such as mobile and ptotic cecum, cecal atony and pericolitis, quite sufficient to explain the patient's symptoms. The age of election for appendicitis appears to be between seventeen and twenty-eight years. Out of 109 cases sixty-eight were in this

range, ten were below seventeen years, and thirty-one were above twenty-eight years. Comparative study of the frequency of constipation and of appendicitis at different ages suggests that constipation is not a factor in the causation of appendicitis. Among appendicitis cases constipation seems to be less frequent than among normal subjects. In forty out of forty-nine cases of acute appendicitis there was no history of disturbed intestinal functions and no sign suggesting abnormality of fecal transit. In forty-one cases, moreover, there was no history of pain, and of the eight patients who had had pain, six were among those who had had diarrhea or constipation. Thus, only eleven patients had had the symptoms—intestinal functional disturbances or pain—which are generally regarded as significant of chronic appendicitis. All the other patients had been in excellent health. Contrary to general opinion, it seems improbable that chronic appendicitis is the basis on which acute appendicitis commonly develops. On the other hand, a number of cases of acute appendicitis, in which no operation was performed, leave behind them disturbances which can be designated as chronic appendicitis. The most severe lesions of the appendix seem to be produced in the first attack of acute appendicitis. In patients operated upon after the second or third attack, the appendiceal lesions were, on an average, much less pronounced than when operated on in the first attack.

Pancreatitis and Its Association with Cholecystitis and Gallstones.—Gilbert Barling (*British Medical Journal*, April 28, 1923) maintains that it is unlikely that fluids may find their way from the duodenum into the bile and pancreatic ducts. It should be remembered that infection may easily spread from the gallbladder down the bile ducts, thence by the pancreatic duct into the pancreas, and that inflammatory processes in the head of the pancreas may compress the ampulla and the terminal portions of the common bile duct and pancreatic duct, producing obstruction to the flow of secretions into the duodenum, causing also some damming of these secretions in the ducts and giving rise to jaundice. He believes that the dominating factor in practically all cases of pancreatitis is infection from the biliary passages, usually, but not necessarily, associated with gallstones. Thrombosis and other factors, such as the adrenals, may play a part, but the presence of infection is the important matter. The most favorable circumstances for the regression of bile into the pancreatic duct would appear to be the impaction of a small stone in the lower end of the ampulla, but in four of the author's cases in which this occurred there was no pancreatitis present. Infection of the biliary passages starts in and from the gallbladder, and is probably an excretory one through the liver. Pancreatitis may range from an intense fulminating widespread condition which kills in a brief period through a gradually descending scale of intensity to a limited dense patch in the head of the organ, producing symptoms mainly of obstruction to the common duct, difficult to discriminate clinically in some cases from carcinoma, and distinguishable occasionally from carcinoma by microscopic examination only.

Mode of Action of Vitamines.—From observations on the pathological lesions induced by vitamine deficiencies, W. Cramer (*Lancet*, May 26, 1923) believes that a mass of evidence has gradually accumulated which points to the digestive tract as the key to the problem of the mode of action of these food accessory substances. The functional integrity of the digestive tract is dependent on the presence in the food of certain substances with specific drug like actions, much in the same way as the functional integrity of the uterus is dependent upon a hormone produced by the ovary. These accessory food substances may therefore be looked upon as food hormones. Two groups with different specific actions can at present be distinguished. One group, now called the water soluble vitamine B, has a stimulating effect on the lymphoid tissue; the other group, now called the fat soluble vitamine A, has a specific stimulating effect on the intestinal mucous membrane, and also directly or indirectly on the formation of blood platelets. These specific effects afford an adequate explanation of the general changes produced in an animal by restricting or completely withholding vitamines from the food. An interesting relationship is thus brought out between an animal and its environment; the food itself contains specific substances on which the integrity of the apparatus responsible for the digestion and absorption of food depends.

The Large Mononuclear Index in Chronic Appendicitis.—L. O. Dutton (*Journal of Laboratory and Clinical Medicine*, April, 1923) carried on under routine conditions a study to determine the value of an increased mononuclear count as a diagnostic aid. In this series of fifty-two cases of chronic appendicitis, about fifty per cent. showed an increase in the mononuclear count. To determine whether a mononuclear increase was to be taken as evidence of an appendiceal lesion, seventy-seven acute cases were studied, which showed only fifteen per cent. with an increase in the mononuclear count. The increase, therefore, is probably not due to the mere presence of an infected appendix, but to the character of the infection (chronic). To find out whether a mononuclear increase was selective for a chronic infection of any site rather than of the appendix only, cases of salpingitis and cholecystitis were studied, showing 30.5 and 46.6 per cent., respectively, with a mononuclear increase over five per cent. Hence the diagnostician should not rely too heavily on the findings of increased mononuclears as a sign of chronic appendicitis, but should bear in mind the possibility of at least two other conditions (chronic salpingitis and chronic cholecystitis) giving the same blood picture.

Experimental and Clinical Observations on Peritonitis.—With the aid of animal experiments L. Schönbauer (*Wiener klinische Wochenschrift*, May 24, 1923) was enabled to show that the subcutaneous tissue resorbs more rapidly than the peritoneum and that the former's powers of resistance against pathogenic germs (anthrax bacilli) is also greater. In this it does not depend upon the number and virulence of the germs only, but upon the extent of the surface over which they are distributed. On the other hand, the capacity for transudation is much greater in the peritoneum than in the subcutaneous tissue and the bactericidal power of the peritoneal transudate is—in so far as the experiments showed—greater than that of the subcutaneous pus.

Clinically, the great surface of the peritoneum should always be taken into consideration, which usually becomes effective with one blow against the invading bacteria. The first requisite is to occlude the portal of entry so that the peritoneum is not overwhelmed. Irrigations with pepsin hydrochloric acid have been found to be useful. Success can be expected from drainage only in the cases where not entirely clean wound surfaces have been left behind in the abdomen. According to the results obtained in the animal experiments, intravenous infusions of salt solution following the operation should be avoided and subcutaneous infusion or the drop enema should be used in its place.

Jaundice in Surgical Cholecystitis Without Stones.—Howard R. Hartman (*Medical Clinics of North America*, July, 1923) states that jaundice in surgical cholecystitis is often erroneously diagnosed as cholecystitis with stones or obstruction of the common duct. The pain, its character, location, and degree, followed by jaundice, leads one to error. The etiology of the jaundice is explained by pancreatitis as definitely as the surgeon is able to determine, and the pain usually by pancreatic colic. All disease of the gallbladder is a panbiliary infection. Removal of the gallbladder frees the patient from a part of the pathological process, but never does it remove all the pathological processes. At present, surgery is the rational treatment, because it removes a mass of infected tissue and automatically makes possible an augmentation of resisting powers to the residual infection. The necessity of removing the primary foci cannot be overlooked.

Calcium and Phosphorus Balance under the Influence of Water-Soluble, Fat-Soluble and Lipoid-Soluble Accessory Food Substances.—P. Rupprecht (*Monatsschrift für Kinderheilkunde*, July, 1923) ascribes the power of increasing the retention power of calcium to the juice of carrots, to codliver oil, and also to the extract of milk deprived of fat. In carrot juice this power is destroyed by heating it to 130° C. in an autoclave, but this is not the case with codliver oil. In regard to the extract of milk deprived of fat, this question is still undecided. The action of the carrot juice and of the codliver oil is independent of the simultaneous presence of other special foodstuffs. It is impossible to ascribe to butter fat any power of increasing the retention of calcium. Attempts at activating the butter fat factor, the factor-A of the American authors, by the addition of vitamines B and C, were without results.

Duodenectomy, with Report of Experiment Four Years After Operation.—Frank C. Mann (*Journal of Laboratory and Clinical Medicine,* May, 1923) removed the duodenum from a dog which remained in perfect health and maintained its normal weight for four years after the operation, at which time it was killed. The continuity of the gastro-intestinal tract was maintained by an end to end anastomosis of jejunum to stomach. The first portion of the jejunum thus assumed the position normally occupied by the duodenum. The common bile duct and pancreatic ducts were transplanted into this transposed portion of the jejunum at approximately the same distance from the pylorus and from each other as they occurred normally. The experiments prove that in the dog the duodenum is not essential to life or good health, and that whatever function it may have can be compensated for by the remainder of the intestinal tract. It also shows that the transplantation of the bile and pancreatic ducts can be carried out successfully so that the respective glands will remain practically normal for a long time.

Treatment of Duodenal Ulcer.—Berkeley Moynihan (*Lancet,* March 31, 1923) states that ninety per cent. of patients on whom a gastroenterostomy was done are cured and the rest are greatly improved. Jejunal ulcers are very diffcult to treat and the author does not know of a single patient who was permanently cured by medical treatment. The following operations may be done: 1, excision of the ulcer with local repair of the anastomosis; 2, excision of the ulcer with closure of the anastomosis; 3, excision of the ulcer, closure of the anastomosis and the establishment of a new anastomosis, anterior or posterior; 4, excision of the ulcer, closure of the anastomosis and a gastroduodenostomy; 5, gastrectomy; and 6, jejunostomy. The prejudice against gastroenterostomy is due to the fact that it has been done indiscriminately, as the results in suitable cases are most excellent. In the aftertreatment of these cases smoking should be interdicted as it is very injurious; many socalled attacks of duodenal ulcer are due to nicotine poisoning.

Etiology of Gallstones.—Symmes F. Oliver (*Journal of Laboratory and Clinical Medicine,* January, 1923) offers the following explanation in cases of gallstones and obstructive jaundice: A disturbance in bile salt secretion and excretion occurs, manifested by an increase in bile salts in the urine and blood and a decrease in the bile salt content of the bile. As a result of the deficiency in the bile salt content of the bile, cholesterin tends to settle out of solution. If the condition is not early remedied, gallstones form the end result of this physicochemical disturbance. Further, the increase in bile salts in the blood leads to toxic changes in other organs, notably the kidneys and heart, and also profound constitutional disturbances of a toxemic nature. In all cases of cholemia, hepatic insufficiency is present. Following operation, the urine becomes normal usually in six to eight days, while the bile reaches normal limits in ten to fourteen days. Finally, cases of this character should be so treated as to restore the bile, urine and blood to their normal physicochemical state.

Treatment of Liver Abscess by Aspiration.—Philip Manson-Bahr, George C. Low, J. J. Pratt and A. L. Gregg (*Lancet,* May 12, 1923) draw the following conclusions: As regards diagnosis: 1. Liver abscess may often be present when scarcely suspected, and may exist in the absence of all suggestive laboratory tests (leucocytosis, pyrexia, the ascertainable presence of Entameba histolytica) and therefore aspiration should be done in case of doubt. 2. A definite leucocytosis may be absent, but even if present, it is not usually high. 3. Pain in the right shoulder may be the most prominent symptom. 4. Liver abscess may exist in the absence of any pain or tenderness referable to the liver area. 5. Entamebæ may or may not be demonstrable in the aspirated pus; their absence or the inability to demonstrate them microscopically does not negative the diagnosis of amebic abscess; neither can these organisms be demonstrated in the feces in every case. 6. X rays may be of considerable help in the diagnosis; immobilization or stretching of the dome of the diaphragm should be regarded as a valuable positive sign. As regards treatment: 1. General anesthesia is not always required, and aspiration may be done successfully sometimes under local anesthesia. 2. All available pus should be aspirated at one operation. 3. Aspiration is followed by a great sense of relief and shock does not occur. 4. Reaccumulation of pus does not usually occur, but if it does, aspiration may be repeated and result in cure. 5. This treatment can be carried out in general practice. 6. The injection of emetine into the abscess cavity is not advisable, but the patient should be treated with large doses of emetine bismuth iodide by mouth.

Pathogenicity and Treatment of Flagellate Dysentery.—Harold E. Whittingham (*British Medical Journal,* May 12, 1923) emphasizes the following facts: 1. Flagellate dysentery is a pathogenic condition which, if allowed to persist, will eventually undermine the health of the patient and cause neurasthenia. 2. Certain cases are simply carriers, as are also some cases of Entameba histolytica infection. This in no way proves their nonpathogenicity. Such carriers are a great source of danger, inasmuch as they may infect others, especially in a military service where the subjects are likely to be drafted overseas. 3. Contrary to what is usually stated, flagellate dysentery may be cured in at least fifty per cent. of the cases. Stress is laid upon the advisability of the combined treatment by purgation, thymol, emetine bismuthous iodide and lavage of the colon. 4. All cases of recurrent diarrhea or neurasthenia for which no cause can be found, and in whom flagellates can be detected in the stools, should have a course of treatment as outlined above.

Ulcer of the Rectum.—Walter Zweig (*Wiener klinische Wochenschrift,* April 26, 1923) states that the prognosis of ulcer of the rectum seems to be favorable as a rule. However, perforations and fatal endings have been reported. The treatment consists of the use of rectal injections of gelatine or of one-hundred grams of warm olive oil mixed with a tablespoonful of dermatol. In a few cases favorable results were achieved with touching of the ulcers with a one to one thousand adrenalin solution. The calcium chloride therapy, which gives excellent results in hemorrhoidal hemorrahges, does not seem to be indicated in simple hemorrhages from ulcers, as it readily leads to tenesmus and pain. Rectoscopic examinations are absolutely necessary, as often these cases are mistaken for hemorrhoids. Besides, the differentiation between ulcer of the rectum and hemorrhagic proctitis can be made only with the rectoscope and only in this way can the suitable treatment be instituted and the proper prognosis established.

NEUROLOGY.

Treatment of General Paralysis by Malaria.—W. L. Templeton (*British Medical Journal,* May 26, 1923) states that the principle of this treatment depends upon the fact that remissions in chronic disease may occur after an attack of an acute specific fever. The method consists in the withdrawal of from two to four c. c. of blood from the vein of a patient suffering from benign tertian malaria in the febrile or afebrile stage and in its subcutaneous injection into the subject of general paralysis, in whom typical attacks of malaria will develop within about a week. He is allowed to have ten or twelve such attacks, when the malaria is cured by the administration of quinine in doses of 1.0 gram for three days in succession; then in doses of 0.5 gram for fourteen days. The malaria usually clears up after the first few doses of quinine. Following upon the febrile attacks and going parallel with the quinine treatment, weekly doses of neosalvarsan are administered intravenously, commencing with 0.3 gram; six doses in all are given, in the scale of 0.3, 0.4, and four of 0.6 gram. In general the histological changes in cases which had shown remission under malarial treatment were those of the socalled stationary paralysis, with an almost complete absence of the changes usually found in progressive general paralysis.

Technic of the Specific Antiserum Treatment of Epidemic Cerebrospinal Meningitis in Narrowing of the Ventricles of the Brain.—K. Lewkowicz (*Monatsschrift für Kinderheilkunde,* April, 1923) states that in severe cases an uninterrupted action of the serum in the ventricles must be provided for in order to achieve a therapeutic effect. If the ventricles are narrowed as a result of edema, not even daily repeated injections even in bilateral application through temporal puncture suffice, because in such cases the serum is washed out from the ventricles very soon by the current of the cerebrospinal fluid. Several intraventricular injections during the day are necessary to get therapeutic results in severe cases.

Importance of Protein Hypersensitivity in the Diagnosis and Treatment of a Special Group of Epileptics.—R. L. Mackenzie Wallis, W. D. Nicol and Maurice Craig (*Lancet,* April 14, 1923) conducted hypersensitivity tests with five groups of proteins to determine the possibility of food poisons or food susceptibility as a factor in the etiology of certain forms of epilepsy. They used the following groups of proteins: 1, egg proteins; 2, meat and fish proteins; 3, the milk of various animals; 4, vegetable proteins; 5, cereals. The question of the best time to do these tests is of the greatest importance. The test succeeds best when the patient is not fatigued, that is, just before an epileptic attack or as long an interval as possible after the previous attack. In private practice the ideal method of treatment is to remove the offending protein or proteins from the patient's dietary, and, if possible, to desensitize the patient by the administration of protein vaccines in small and graduated doses.

Of one hundred and twenty-two epileptics tested, forty-six gave positive reactions to different proteins, and seventy-six gave no reaction at all. The special group appears to be quite healthy, usually inclined to obesity and not excitable or markedly unstable, and gave positive tests. The fact that they do not respond to bromides is characteristic of this group. The results of these tests show conclusively that in some cases where it is possible to adjust the diet on the basis of skin tests, no further treatment is necessary. In some cases where peptone was given by mouth, the fits became less frequent and in some cases of associated insanity there was mental improvement as well. A very few cases became decidedly worse with peptone treatment. These tests may be used as a guide not only to treatment but also to diagnosis.

Radiographic Localization of Spinal Lesions by Sicard's Method.—Percy Sargent (*British Medical Journal,* August 4, 1923) describes Sicard's method as follows: A small quantity, between one and two c. c., of lipiodol is injected into the spinal theca through a suboccipital puncture, the patient being in a sitting posture. Lipiodol is a heavy oily fluid consisting of poppy oil containing forty per cent. of iodine, and is remarkably opaque to the x rays. The lipiodol sinks slowly downward and is arrested at any point of occlusion of the spinal theca, so that the upper limit of a tumor, for instance, can be accurately demonstrated by x ray examination. Similarly, the lower limit of such a tumor can be shown by injecting the lipiodol through a lumbar puncture, and taking a radiogram with the patient in the head down position. The value of Sicard's method is obvious. Not only can it be employed to ascertain whether or not a block exists in the spinal theca, but it shows the exact position of the lesion with relation to the bones. From the operative viewpoint the localization is more accurate than that which can be arrived at by neurological examination. A radiographic demonstration of the relation of the lesion to the vertebrae is of great value and enables a tumor to be exposed by the removal of perhaps only three laminal arches. If the upper limit of a tumor having been defined, a second examination is made by taking a radiogram with the patient placed head downward after injecting lipiodol through a lumbar puncture, the lower limit of the tumor can also be demonstrated. This is a matter of considerable importance to the surgeon, since tumors extending over many segments are sometimes encountered.

Treatment of Tetany with Ammonium Phosphate.—D. Adlersberg and O. Porges (*Wiener klinische Wochenschrift,* July 19, 1923) obtained excellent results in the treatment of tetany with ammonium phosphate. The galvanic excitability was always diminished in a short period of time and the symptoms of tetany were completely relieved. This result did not originate from the gastrointestinal tract without the substance being resorbed, as has been claimed, but the reduction of the carbon dioxide tension of the alveolar air, the diminution of the alkali reserve, and especially the excretion of the urine of phosphate which is increased several times above the normal, show that this substance is resorbed and acts by way of the blood. The acid ammonium phosphate is a very effective remedy against tetany, which is well borne and taken readily. Eighteen grams are given daily in a litre of water plus some flavoring vehicle. The results are prompt, appearing on the first day after its administration. The subsequent doses may possibly be diminished.

Von Wagner's New Treatment of General Paralysis.—Alexander Pilcz (*Lancet,* January 6, 1923) treated 141 paretic patiets according to the following method: A patient is selected who suffers from tertian malaria (but not from tropical malaria) and who has not been treated by quinine (in order to avoid quinine fast stems of plasmodia). During an attack of fever, two c.c. of blood are taken from the patient by venous puncture, and injected underneath the skin of the paralytic patient's back. After an average of one to two weeks, the first attack takes place, accompanied by shivering; the temperature rises to 40° C. and over. After some ten or twelve attacks the malaria is checked by quinine during the first three or four days (0.5 gm. quinine sulphate twice a day for three or four days, and then once daily for two weeks); at the same time a course of neosalvarsan is begun (intravenous injection once a week, commencing with 0.3 gm., and working up to 0.6 gm.). During the malarial attacks, acoustic hallucinations, ideas of persecution and deleterious and catatonic states are occasionally noticed, but all these symptoms will cease when the quinine course of treatment is started. This treatment should be applied not only when the general paralysis is already manifest, but also much earlier, in any case of secondary syphilis.

Relationship of Acid and Alkali in Tetany.—Herb. Elias (*Wiener klinische Wochenscrift,* October 5, 1922) finds that the disturbances in the acid metabolism play no important part in the pathogenesis of tetany in adults. The question of the pharmacological influence upon tetany by acid and alkali is by no means settled. Up to the present time, the following may be said of the results of investigations, concerning which there is still considerable dispute: 1. Very large amounts of acid increase the irritability of nerves in man and in animals. 2. Small amounts of acid seem to diminish the tetanic irritability. 3. Alkalies seem to increase them. 4. The phosphoric acid ion increases the nervous irritability in normal and in tetanic individuals and animals. This increasing of the nervous irritability through the action of phosphoric acid is more intensive than the inhibitory action of small doses of acid.

Causes of Headache.—A. B. Pavey-Smith (*Lancet,* September 8, 1923) classifies the causes of headache as follows:

INTRACRANIAL.

A. Cortical—Headache arising in the sensory cortex. 1. Functional—hysteria, neurasthenia, migraine (hemicrania). 2. Organic—disseminated sclerosis. B. Dural—Headache due to irritation of nerves of dura mater. 1. Intracranial pressure—a. Raised by: a. Hyperemia. i. Active—e. g., head injury; fevers; nephritis; bacterial toxemias; fatigue, reaction after syncope; poisons (lead, alcohol, etc.); anemia. ii. Passive—e. g., asphyxia; heart disease. iii. Cerebral edema; head injury; sunstroke. iv. Increase of cerebrospinal fluid.—Hydrocephalus; meningitis; head injury. v. Increase of cranial contents.—Tumor; cyst; gumma; abscess; extravasated blood. b. Lowered by deficiency of cerebrospinal fluid—headeache due to pressure of unsupported brain on basal dura and tentorium. i. Leakage.—Lumbar puncture. ii. Hyposecretion.—Anemia. 2. Inflammation.—Pachymeningitis, localized suppurative meningitis, subdural abscess, general paralysis of the insane.

CRANIAL.

A. Bone disease.—Headache due to irritation of periosteal or dural nerves. Osteitis, Periostitis, Extradural abscess—e. g. infected fractures; extensions of otitis media; syphilitic necrosis. B. Nasal sinuses.—Headeache due to irritation of nerves in mucosa lining. Sinusitis and Retention.—Headache without other symptoms or with nasal catarrh or obstruction "Excitable" Sinus.—Constipation; toxemias; menstrual. Pain arising in the middle ear and mastoid is not included under headache.

EXTRACRANIAL.

Headache due to irritation of nerves or nerve-endings outside the cranial wall, and referred. 1. Ocular.—Muscular fatigue—errors of refraction. Hypertension—glaucoma. Inflammatory—iritis. 2. Dental.—Frontonasal headache referred from upper incisors—Dental caries. 3. Nasal.—Pressure on septum—headache with nasal obstruction. Meckel's ganglion inflammation—sphenopalatine syndrome. 4. Neuralgic.—Irritation of branches of fifth or other scalp nerves—Trigeminal neuralgia; cervical caries (occipital). 5. Rheumatic.—Inflammation of muscle or aponeurosis of occipitofrontalis—myositis; muscular rheumatism.

Medicolegal Notes.

DEATH BY POSTOPERATIVE SHOCK HELD COMPENSABLE

An employee who sustained injury by accident arising out of and in the course of his employment received medical attention from his employer's physician; the latter, and also a surgeon employed by the employer, advised a surgical operation as the only means of relieving the employee's condition, which he was informed was stone in the kidney, and the result of his accident. The employee consented to the operation, which was performed by the employer's surgeon at the employer's expense. The employee died of postoperative shock as a result of the operation. The operation showed that the employee had been suffering, not from stone in the kidney, but from a calcareous tubercular suprarenal gland of the right kidney, a condition not caused by the injury. For this reason, the employer contended, in proceedings under the Indiana Workmen's Compensation Act, that the causal connection between the employee's accident and his death was broken, and his death was not the result of his injuries. The Indiana Appellate Court holds, National Rolling Mill Co. v. Kish, 139 N. E. 454, that the death was the result of the accident, and so compensable.

WHAT CONSTITUTES A DIAGNOSIS

In sustaining the conviction under the California statute of 1917, p. 114, §17 of a chiropractor for practicing without a license, the California District Court of Appeals, in People v. Willis, 217 Pac. 771, rejected the accused's claim that he could not be legally convicted because in his practice he did not "diagnose" human ailments. The court said that "it is difficult to conceive of any one trying to restore to a normal condition a person who is abnormal without a prior investigation and determination, in a general way, at least, of the character of his abnormality. Manifestly, there are no fixed limits to a diagnosis. It may not amount to a scientific classification of the ailment, but it may go further than an observation of the most obtrusive symptoms, and may be accurate or inaccurate, and yet be within the contemplation of the statute. It seems like an aspersion on the character and intelligence of this respectable body of practitioners to intimate that they attempt to restore 'the normal activity of the tissues' without any inquiry or investigation as to what tissues are affected and in what manner their activity may be abnormal."

Moreover, under the California statute, the defendant would be equally guilty in giving treatment without a diagnosis.

EXAMINATION OF PODIATRISTS DOES NOT APPLY TO MEDICAL PRACTITIONERS

Act of Congress of May 23, 1918 (40. Stat. 560) providing for examination of those practising podiatry for compensation in the District of Columbia, makes an exception of "regular practicing physicians or surgeons." The Court of Appeals of the District of Columbia, Howerton v. District of Columbia, 289 Fed. 628, holds that osteopaths, entitled to practice in the District of Columbia, are included in the exception.

The court is of opinion that "the act is not intended to interfere with the general practice of any recognized branch of medical science; nor that a general practitioner, in any established branch of medical science, shall be limited in the treatment of his patients to all parts of the body except the foot, which, except in cases of surgical treatment, shall be reserved for the podiatrist." The act defines podiatry or chiropody to be "the surgical, medical or mechanical treatment of any ailment of the human foot, except the amputation of the foot or any of the toes, and also except the use of an anesthetic other than a local one."

LIMITS OF AUTHORITY OF INSURANCE COMPANY'S EXAMINING PHYSICIAN

Where a physician is employed by a life insurance company merely for the purpose of making a medical examination and a report thereof to the company, and has no other duty or authority with reference thereto, the Ohio Supreme Court holds, Myers v. Hancock Mut. Life Ins. Co., 140 N. E. 504, that subsequent knowledge of such physician with reference to the changed physical condition of the applicant examined by him prior to the approval of the application and issuance of the policy, and uncommunicated by him to the company, is not binding upon the company, nor does it constitute a waiver of the provision of the application that such policy shall become effective upon approval at the home office of the company "while the person to be insured is in the same condition of insurability."

UNANSWERED QUESTION AS TO PROTECTION AGAINST MALPRACTICE ACTIONS BY MEDICAL ASSOCIATION REVERSIBLE ERROR

In an action for damages for malpractice in treating the plaintiff's toe, which it was alleged resulted in the necessary amputation of the leg, the plaintiff, in making his case, on cross examination of the defendant asked him whether he was a member of the Northwestern Medical Association. Being answered in the affirmative, he further asked if the defendant had reported the case to the association, and whether it was not one of the purposes of the association to protect doctors against malpractice actions. The North Dakota Supreme Court holds, Stoskoff v. Wicklund, 193 N. W. 312, that the asking of these questions constituted prejudicial error, requiring a new trial, even though the objections interposed by the defendant to such questions were sustained by the trial court, and the witness was not required to answer them.

The mere fact of the loss of a leg under the care of a physician, although negligence on his part is established, is not in itself sufficient to sustain a verdict for damages, in the absence of evidence tending to show that such loss was the proximate consequence of such negligence.

PREEXISTING DISEASE AGGRAVATED BY ACCIDENTAL INJURY

In proceedings under the Illinois Workmen's Compensation Act for the death of an employee following a fall while unloading a car of roofing paper, a witness for the applicant, one of the two physicians who performed the autopsy, testified that in his opinion death resulted from hypostatic pneumonia and meningitis, conditions aggravated or accelerated by the injuries received. The other physician, a witness for the employer, agreed in the main with this testimony as to the physical conditions shown by the autopsy, and stated that the death might or might not have been due to the injury. The Illinois Supreme Court held, Great Lakes Supply Co. v. Industrial Commission, 140 N. E. 2, that the findings and award of compensation by the Commission were not against the manifest weight of evidence. The court states the rule in Illinois to be that: "Where an employee dies from a preëxisting disease and the disease is aggravated or accelerated by an accidental injury, or an injury which produced pneumonia or other disease which aggravated or accelerated such preëxisting disease, the death may be said to be caused by accidental injury."

Insulin in the Treatment of Diabetes

With a Note Upon the Effect of Colds in Cases of Diabetes.

HENRY J. JOHN, M.D.,
Cleveland,
Cleveland Clinic

The following report, with accompanying charts, is offered to illustrate my experience to date in the use of insulin, regarding the effects of which at the time I began using it in September, 1922, there was practically no clinical information. Each investigator, therefore, has had to learn its effects for himself from his own observations and laboratory data. The accompanying graphic charts are offered as the best means of grouping and correlating the different factors which are involved in the progress of a case of diabetes, and as the best method of visualizing the effects of any particular form of treatment.

I wish to extend my most hearty thanks to Dr. Clowes, of the Research Department of Eli Lilly & Co., whose cordial cooperation has made possible this investigation. For a period of about six months, this company supplied to us without cost as much insulin (under the trade name, iletin) as we could use.

Small doses were given at first, the effects of each dose being controlled by a blood sugar estimation. Later larger doses were employed and when it was found that the patients could take these safely, I finally ventured to use doses of fifty units each. Throughout my investigation the insulin has been given intravenously, for the simple reason that I can give the injection and then withdraw blood for the blood sugar estimation without changing the syringe, so, unless it should be proved that subcutaneous doses offer a distinct advantage, I shall continue to use this method. It is interesting to note that even the large dose of fifty units rarely produced a reaction. I have given this dose twice a day and on some occasions have even added a third smaller dose without observing any reaction. On the other hand, two of the most severe reactions that I have seen followed much smaller doses of insulin, namely twenty and eighteen units. Fortunately, during this whole experimental period, I did not meet with a single accident. It was a clinical venture into the unknown, and I felt that it was my duty to learn all I could during this time. I am not advocating maximal doses. That was but a part of the program of study, an attempt to see how large doses could be used with safety. Here I am offering a few of the cases that were studied, with an attempt to interpret the effects. While my interpretation may be disproved, as with time our knowledge of the action of insulin increases, on the other hand, the data—the doses used and their effects—will remain unchanged and I trust will add to our understanding of this new and splendid remedy.

FIG. I.—Patient in Case I.

An interesting phase of the relationship of the blood sugar content to insulin is illustrated in Charts I and II. Chart I represents the fall and rise of the blood sugar of a diabetic, thirty-two years of age, on a diet of forty-five gm. of carbohydrate, forty-five gm. of protein, and a total of eleven hundred calories a day. The chart shows the changes following breakfast and lunch, the quantities of food taken at each meal being stated on the charts.

Following an ordinary meal, we get much the same reaction as we do following a hundred gm. of glucose in the glucose tolerance test, the length of the hyperglycemia depending on the severity of the diabetes, namely, after each meal there is a rise in the blood sugar content followed by a gradual fall, until in three hours the blood sugar curve has nearly returned to the level at which it started.

In a diabetic, therefore, the hyperglycemia following meals is higher than that of the fasting state which persists throughout the rest of the day. The main question, therefore, in the use of insulin is, will insulin reduce

Copyright, 1924, by A. R. Elliott Publishing Company.

this quotidian hyperglycemia? With this point in view, the next day, I kept the man whose blood sugar curve is given in Chart I, on identically the same routine, as to diet, but added two injections of insulin, one of twelve units before breakfast and one of fifteen units before lunch.

The fasting blood sugar when this second test was made was 222 mg. to the 100 c.c., as compared with 192 mg. to the 100 c.c. on the previous day. Yet, as Chart II indicates, the blood sugar promptly dropped below the normal level and remained below normal for the rest of the day. In this case, then, insulin accomplished the ideal result, i. e., it reduced a state of hyperglycemia to normal glycemia and kept it normal throughout the day.

Twenty minutes after the first injection of iletin, there was a slight reaction which manifested itself by the pounding of the heart and a subjective "shaky feeling." This lasted one hour. About five minutes after the second injection, when the blood sugar was forty mg. to the 100 c.c.—a reading which, of course, had not been made when this injection was given or it would have been omitted—a second reaction set in. With the blood sugar at such a low level one would expect a further drop, and a severe reaction, such as McLeod and his coworkers observed in animals. Yet this was not the case. The reaction was of the same intensity, duration, and character as the first. It should be noted, however, as a possible explanation of the mild degree of the second reaction, that it set in during the period of the usual postprandial rise of blood sugar.

From this brief study I think that we can reasonably conclude that in this case the hyperglycemia can be kept in check by the use of insulin, and that in time the patient's tolerance for carbohydrates may perhaps be increased. It shows also that hypoglycemia is not necessarily an absolute contraindication to insulin. Whether or not in this latter case it does any good to the patient is another question.

REPORTS OF CASES.

Case I.—The patient was a little girl, four years old, with no familial history of diabetes. She had measles in February, 1922, following which she began to fail. In May, a marked polyuria developed, with thirst, and shortly afterward sugar was discovered in the urine. She was put on a restricted diet, but she continued to fail. I was called to see her on December 21, 1922, when she was failing so rapidly that they thought she was going to die. I found a fretting and sleepy emaciated youngster with acetone breath, weighing only 26.4 pounds. Her blood sugar was 440 mg. to the 100 c.c.; there was a marked acetone reaction in the plasma and a very marked lipemia. The urine contained 6.9 per cent. sugar. (Fig. 1.)

I began the intravenous administration of iletin in small doses, viz., three units a day, given in the morning before breakfast. The child responded promptly, so that in three days her blood sugar had dropped to 150 mg. to the 100 c.c. The following day was Christmas and she ate some candy, as the result of which her blood sugar increased to 242 mg. to the 100 c.c. Two subsequent doses of iletin of four units each made no impression on the blood sugar, which in fact, began to rise gradually. On December 28th, the child was transferred to our diabetic hospital, and since then her diet has been carefully controlled. One may follow the progress of the child best from the graphic chart (Chart III). Under the increased doses of iletin—she never had a reaction—in about two weeks her blood sugar reached the normal level, and with three slight exceptions it has remained normal without iletin.

During that time she had a diet of 1,000 calories, which was quite sufficient for a child of her years; she began with thirty gm. of carbohydrate, which was gradually increased to seventy gm. The best proof that this diet had been sufficient for her was the fact that she gained weight gradually. Another point of interest in this case was that although the patient's blood sugar was normal, or below normal, she was still excreting considerable quantities of sugar in the urine. This would appear to indicate that her kidney permeability to sugar was low. Nevertheless, although I did not make a glucose tolerance estimation, I doubt very much whether the permeability was below normal. What probably happens is this: After each meal, just as after the ingestion of glucose for the glucose tolerance test, the blood sugar content is increased for varying periods of time; in all probability, therefore, during this period of postprandial hyperglycemia, the sugar spills into the urine, thus accounting for the varying quantities excreted daily. Without a glucose tolerance estimation this could not be stated as a fact, but on the basis of past experience, this seems a logical conclusion.

There is another point of interest in this case, which should be borne in mind in connection with any case of diabetes. On March 31st, the child contracted a cold, after which the blood sugar rose promptly. I have observed a similar sequence more than once among my diabetic cases. In this case the cold continued, bronchitis developed, and a reduction in diet was necessary. Iletin was given until the blood sugar dropped to the proper level and the infection subsided. The patient's weight decreased with the rise of blood sugar, but now she is gradually gaining again. Following this infection the urine sugar output for twenty-four hours has increased which probably means that postprandial hyperglycemia is more prolonged than before. Whether or not permanent damage has been done by this infection it is too early to say; often such a cold does permanently interfere with the progress of a diabetic patient, especially if it is not dealt with promptly.

Case II.—The patient was a boy, fifteen years of age, a factory worker, who gave no familial diabetic history, and no history of any children's diseases. He had been perfectly well until three months before he came to the clinic in June, 1922, when he began to have great thirst and polyuria. During these three months he lost about thirty pounds in weight. His skin had become dry, with an eruption but no boils. He used to be a heavy eater of sweets. There was no history of any infection preceding the onset of diabetes. He had had some swelling over the ankles. His mother said that on some days he was very sleepy.

The boy presented a picture of a beginning coma. He was markedly thin and very weak. He had an

ichthyotic skin, labored respiration, and a marked acetone breath; he was sleepy, and hard to arouse; one had to repeat questions put to him and then he answered with difficulty. The blood pressure was 110-65; otherwise the physical examination was negative. The blood sugar was 447 mg. to 100 c. c.;

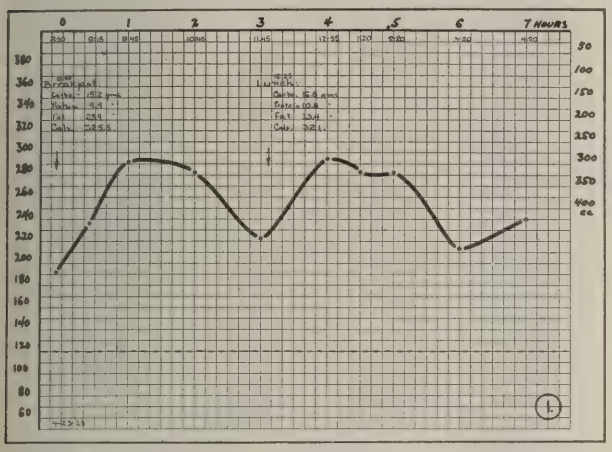

CHART I.—Blood sugar curve of a diabetic on a diet of forty-five grams each of carbohydrate and protein.

there was marked lipemia; marked acetone reaction in the plasma; the CO_2 tension in the plasma was twenty-six mm. Hg. The urine showed 1.3 per cent. sugar, and a marked reaction for acetone.

The boy's diet was gradually diminished, and he was given repeated small doses of iletin. For nearly two weeks, during which his diet remained the same, the blood sugar level dropped to about 250 mg. to 100 c. c. and remained at that level. After a further reduction in his diet the blood sugar content was diminished further. The patient was discharged on October 28th with a blood sugar content of 136 mg. to 100 c. c. He returned two weeks later for a blood sugar estimation, at which time it was 174 mg. to 100 c. c. He continued on the same diet and two weeks later his blood sugar content was 112 mg. to 100 c. c. I then raised his diet—chiefly the fats—to twenty-five mg. carbohydrate, thirty-five mg. protein, a total of 1,800 calories. When he returned two weeks later his blood sugar was 294 mg. to 100 c. c., but in spite of this high fat diet there was not a trace of acetone in the plasma. His urine was loaded with sugar. His diet was cut down to fifteen gm. carbohydrate, twenty gm. protein, a total of 1,000 calories, but when he came again two weeks later his blood sugar was 288 mg. to 100 c. c., there was acetone in the plasma, lipemia was 3 plus, and his urine was loaded with sugar. It was strange that lipemia and acetonemia should develop when the fat in his diet had been diminished practically one half. At this stage his diet was still further diminished, namely to ten gm. carbohydrate, twenty gm. protein, a total of 400 calories. When he came back three weeks later his blood sugar was still higher—316 mg. to 100 c. c., there was no lipemia, but the urine was loaded with sugar. The patient was again put in the hospital, on a low diet and iletin, but all this made but little impression on the blood sugar content. The blood sugar level would fall a little after the administration of iletin, but the reduction was only temporary; by the next morning the blood sugar level would again be raised. With the small quantities of carbohydrate intake at this period, and the large iletin doses each day, the blood sugar of even a total diabetic should have been kept at the normal level.

The course of this case, which presents such a contrast to Case I, raises the question as to whether small doses of iletin may not burn up the sugar while larger doses stimulate the mobilization which appears in the blood stream. A comparison of the urinary sugar output during this second period with that during the first shows that it has greatly decreased. This also seems surprising for the blood sugar level is practically unchanged. The glucose tolerance curve, however, gives the explanation, namely, that the renal filter is becoming less and less permeable (Chart IV). This patient did not return for further treatments, unfortunately, so that we do not know the outcome of the case.

CASE III.—The patient was a man, twenty-two years of age, with no familial diabetic history. He had had measles, whooping cough, chickenpox, mumps; he had had scarlet fever at the age of ten years, gonorrhea and suppurating orchitis. He complained of violent thirst, loss of weight, frequency of urination, swollen feet and ankles, defective vision and nervousness. A month before he came to the clinic sugar had been discovered in the urine. At that time he had lost about thirty pounds in weight during the preceding one and a half months. Physical examination was negative. Upon his admission to the clinic the blood sugar was 490 mg. to 100 c. c., and the urine heavily laden with sugar—he excreted 40.33 gms. in twenty-four hours.

The best picture of the patient's progress in this case is shown by the graphic record (Chart V). As is shown there on the first day he received three doses of iletin, of 8, 16, and 25.6 units, respectively, and in the short period between 10 a. m. and 3 p. m. his blood sugar reached the normal level. He was dis-

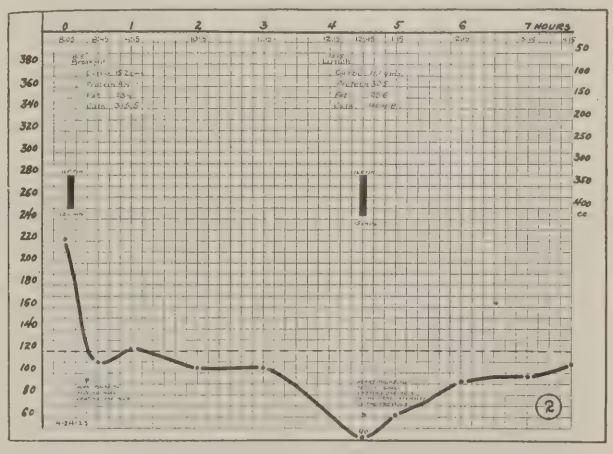

CHART II.—Blood sugar curve of same man as in Chart I, on the same diet with two injections of insulin.

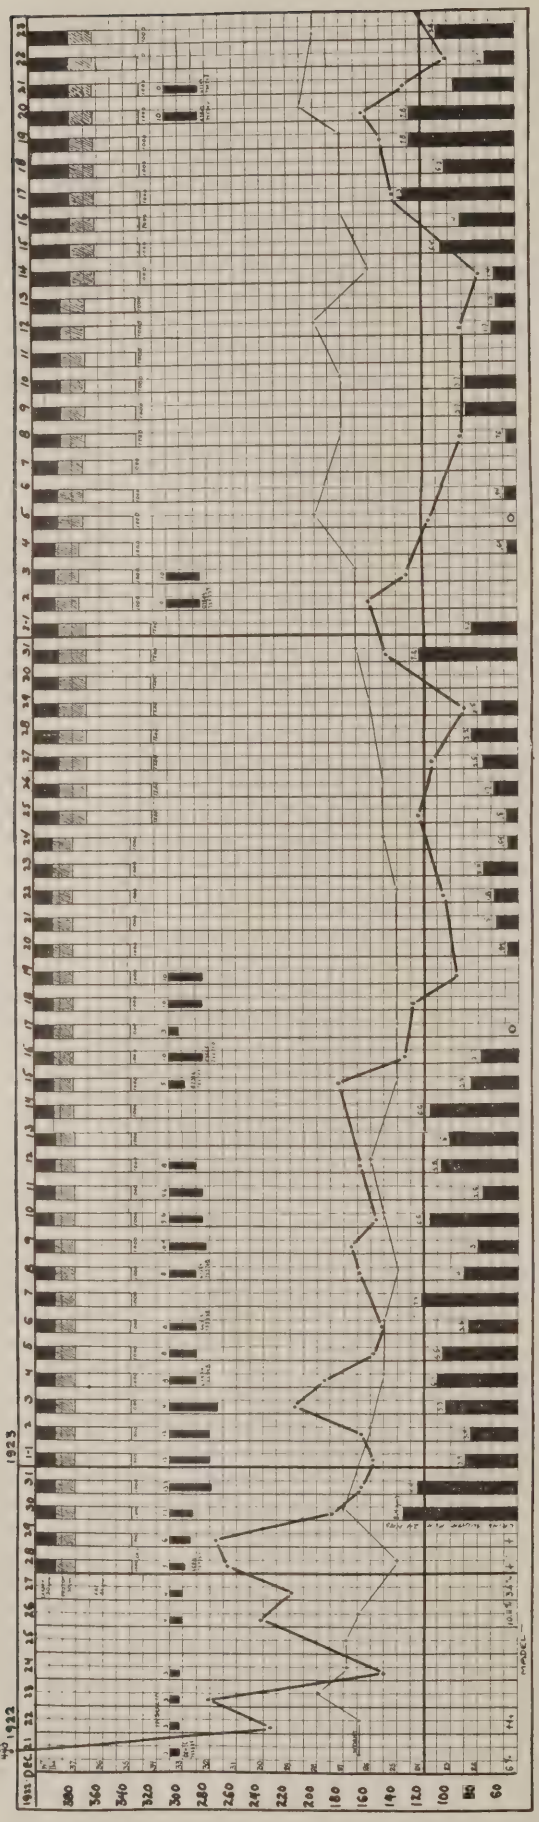
charged from the hospital two weeks after admission, with a blood sugar content of 96 mg. to 100 c. c., on a diet of fifty gm. carbohydrate, forty gm. protein, a total of 1,500 calories. He has been working hard ever since and is now taking fifty-five gm. carbohydrate, forty-five gm. protein, a total of 1,800 calories. He feels well and his blood sugar remains at the normal level.



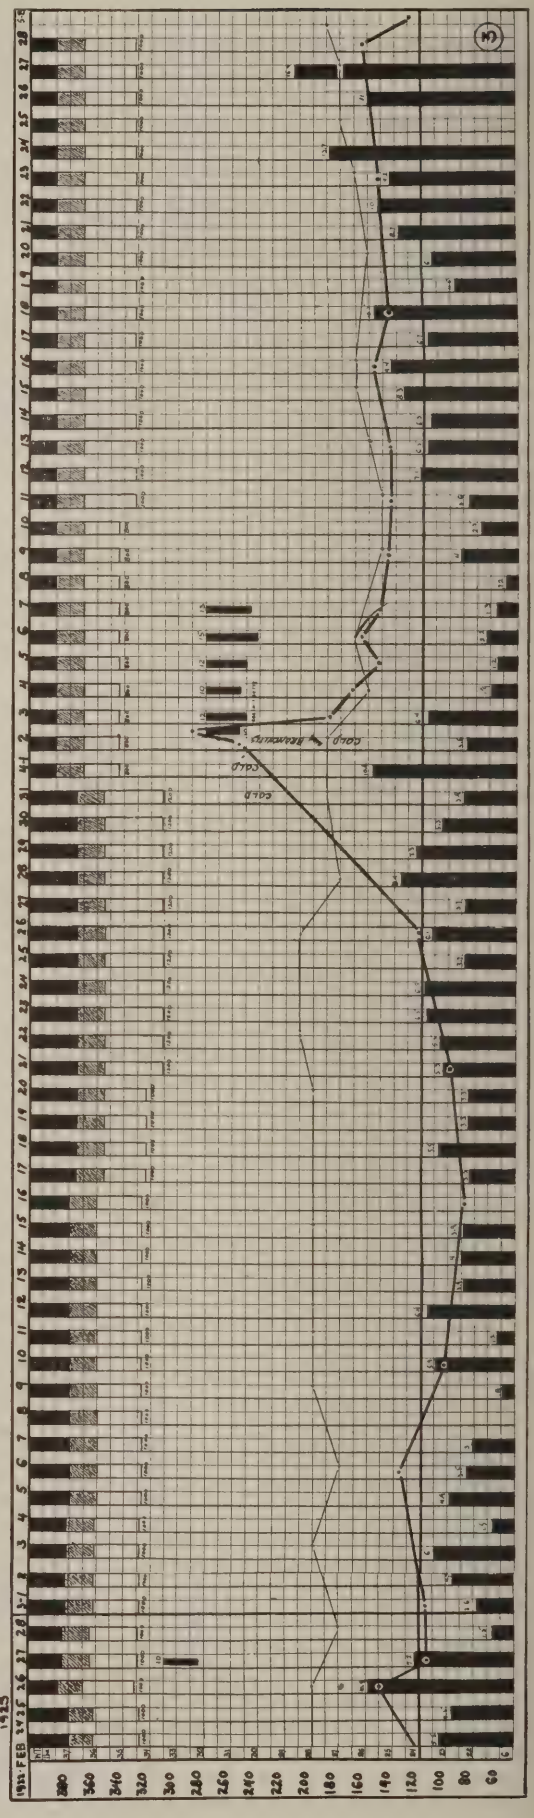


Chart III.—Blood sugar curve of patient in Case I.

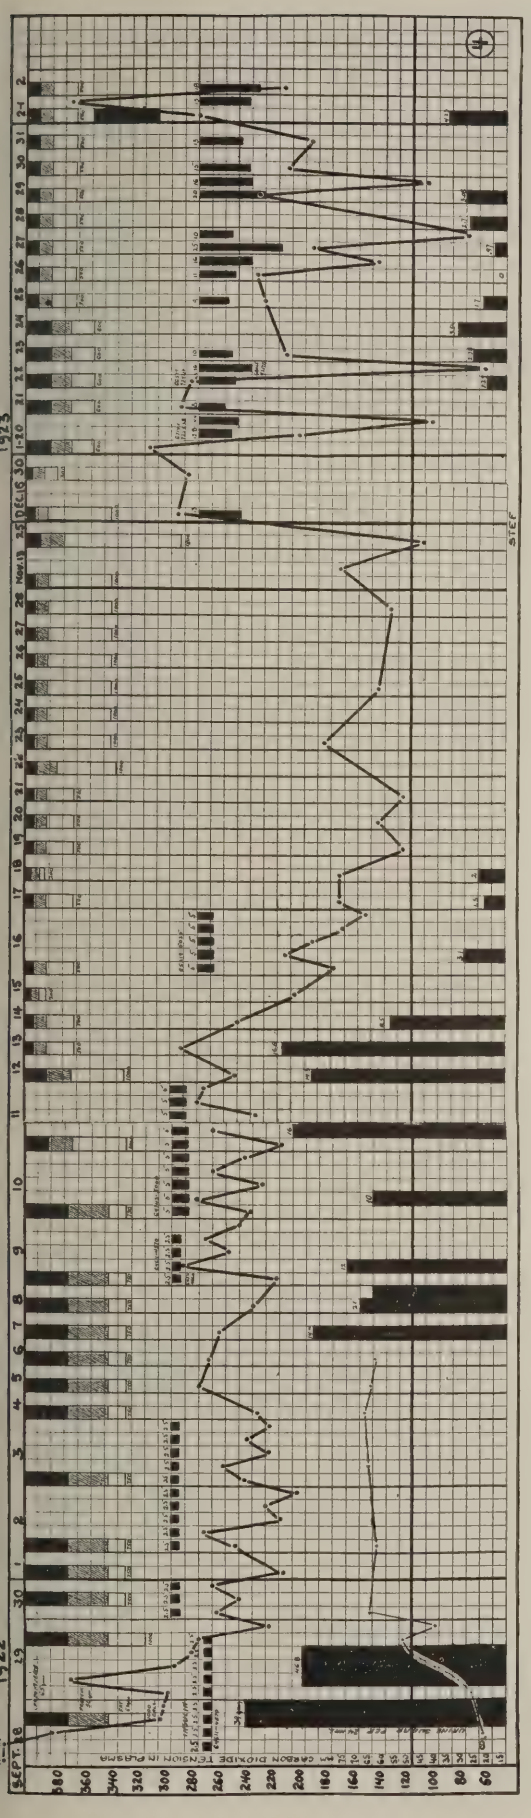

CHART IV.—Blood sugar curve of patient in Case II.

CASE IV.—The patient was a married woman, fifty-three years of age, with no familial history of diabetes. She had had scarlet fever in childhood, and a suspension of the uterus six years before. She complained of shortness of breath, which had increased progressively during the last ten years. This was so pronounced that even the slight exertion of walking made breathing difficult and she was unable to walk up stairs. It was harder for her to get air into the lungs than to let it out. She was obliged to use two pillows at night. She coughed when she was short of breath and at times had coughing spells, particularly when combing her hair. She had pain in the right side of the neck leading up to the ear, and had been very nervous during the past three weeks. There was no swelling of the feet; no stomach disturbance, no loss in weight.

Physical examination showed a large, stout woman, with eyes and teeth in fair condition, and throat sound. She had quite a large, firm goitre, which seemed to descend into the superior strait of the thorax. She breathed much better with her head thrown back, having choking spells when her head was bent forward. Her heart was enlarged to the left; sounds were clear; blood pressure, 170-110; abdomen full and large; liver not enlarged. The x ray examination revealed a substernal goitre. Blood examination showed blood sugar 200 mg. to 100 c. c. and she also had sugar in the urine. After her return home she caught cold, the mucosa of the larynx and bronchi swelled, she became extremely cyanotic and there was danger of her choking to death. She was brought back, given inhalations, etc., and received two doses of iletin, eight units each, the first day. The next day her blood sugar was normal. A thyroidectomy was performed the next day and an uneventful recovery followed. She was discharged from the hospital on the sixteenth day on a diet of sixty-five gm. carbohydrate, forty-five gm. protein, a total of 1,800 calories. When she returned a month later her blood sugar was normal. (Chart VI.)

Apparently this was a mild case of diabetes in which the preoperative control of the blood sugar was of distinct service to the surgeon.

CASE V.—A physician, sixty-one years of age, leading a very active life, gave no history of any diseases, or operations, but said that after an epidemic of influenza, in which he had worked very hard, he was not able to recuperate properly; he became tired easily and caught cold readily; he slept poorly and did not feel refreshed when he did sleep. He had discovered sugar in his urine several years before and had been on a partially restricted diet ever since. On October 17, 1922, his blood sugar was 232 mg. to 100 c. c. and the urine showed 2.3 per cent. sugar.

On the day on which he was admitted to the hospital his blood sugar was 250 mg. to 100 c. c. At 3 p. m. he was given sixteen units of iletin, and at five, when eight more units were administered, his blood sugar had dropped to ninety-two mg. to 100 c. c. A rapid improvement followed these injections of iletin, the progress being shown best by the graphic record (Chart VII). Six days after his entrance the patient was discharged from the hospital on a diet of thirty-five gm. carbohydrate, forty five gm. protein, 1,500 calories, and he has been

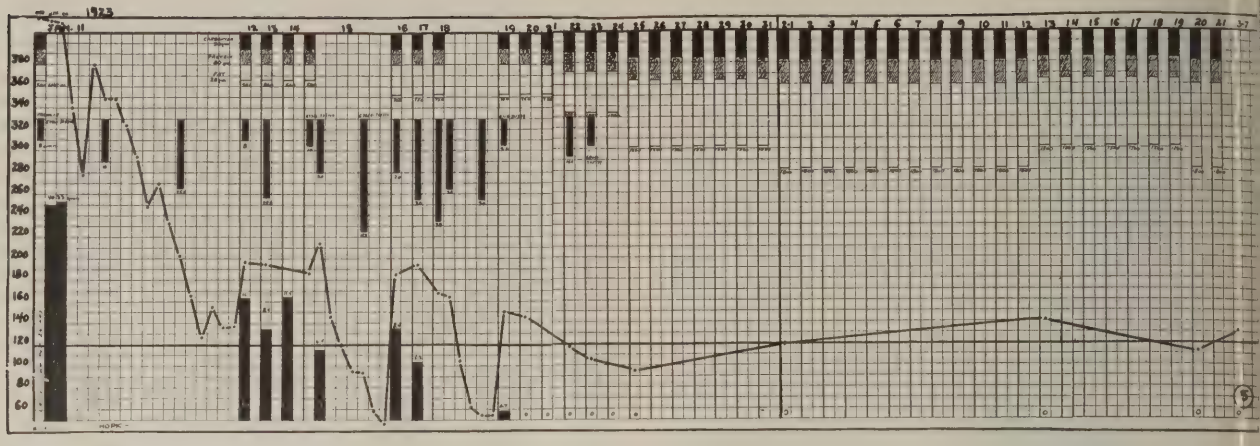

CHART V.—Graphic record of patient's progress in Case III.

working hard ever since carrying his country practice. Subsequent blood examinations have shown a normal blood sugar content, and at present he is on a diet of seventy gm. carbohydrate, fifty gm. protein, 2,000 calories, feeling well, and leading a very busy life. The striking point in this case is the rapidity with which the blood sugar content became and remained normal and the continued progress to date on an increasing diet.

CASE VI.—The patient was a laundryman, single, twenty-eight years of age, with no familial history of diabetes. He had had no childhood diseases, no operations. He complained of loss of weight, loss of strength and frequency of urination. While in the army overseas, he had been gassed. Three months before he had noticed dizziness, thirst and polyuria, because of which he consulted a physician who found sugar in his urine. He was put on a restricted diet and improved somewhat, but he had lost about twenty-two pounds during the last three months. Physical examination showed a thin, emaciated patient with a dry skin. Other physical findings were negative. Laboratory examinations showed he had 3.4 per cent. sugar in the urine, which also gave a heavy acetone reaction. His blood sugar was 485 mg. to 100 c. c., and acetone was present in the plasma. There was also a marked lipemia.

When the patient entered the hospital on January 11, 1923, his fasting blood sugar was 696 mg. to 100 c.c. The treatment and its results are shown in Chart VIII. It is interesting to note that in spite of the large doses of iletin given on January 15th and 18th—eighty-six and ninety units respectively—there was no reaction. This was a very severe case of diabetes and the blood sugar returned very gradually to the normal level. The patient's glucose tolerance at this time is shown by the following findings in a glucose tolerance test made on February 1st:

Mgm /100cc	Before administration of 100 gm. of glucose	half hour after	one hour after	two hours after	three hours after	four hours after

Wassermann—neg.

After January 29th he had a series of repeated colds; moreover, he was discharged from the hospital

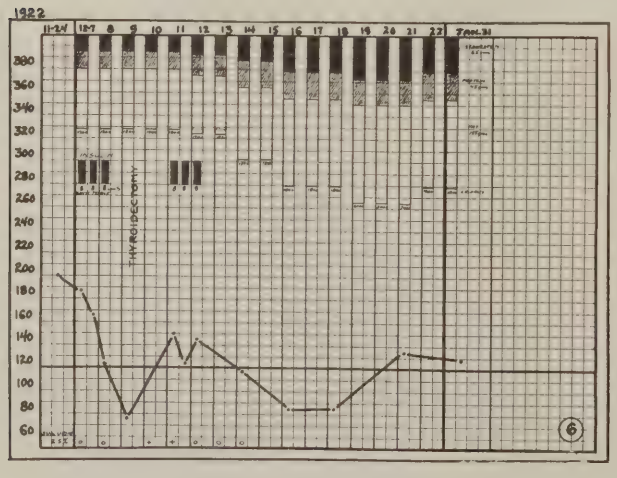

CHART VI.—Blood sugar curve of patient in Case IV.

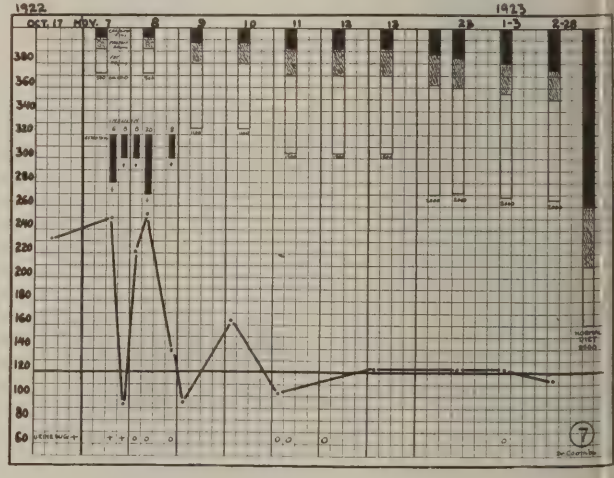

CHART VII.—Graphic record of progress of patient in Case V.

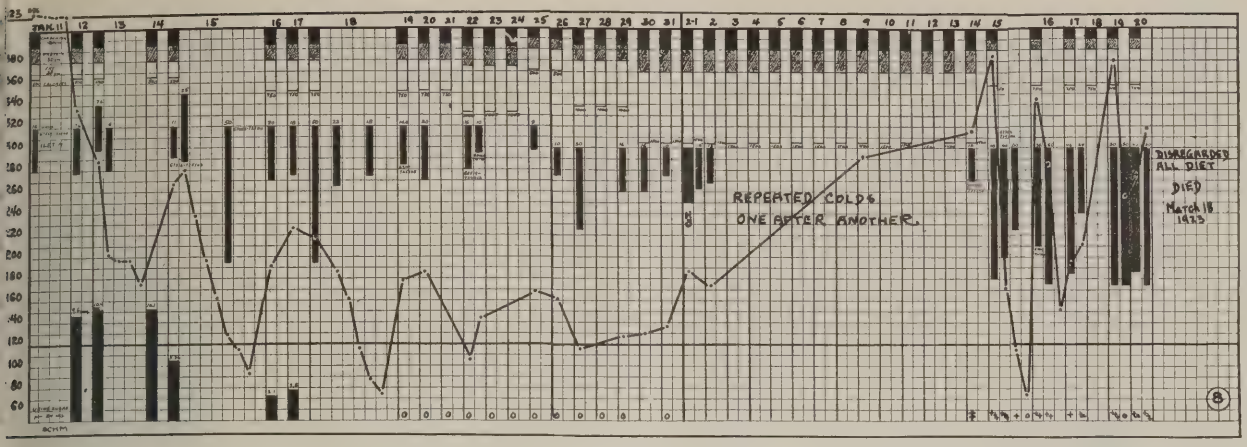

CHART VIII.—Showing results of iletin treatment in Case VI.

in February 2nd and it is doubtful whether he adhered closely to the prescribed diet after his discharge, although he knew how to calculate the proper proportions of protein, carbohydrates and fats. These colds, together with probable overeating, raised his blood sugar to 384 mg. to 100 c. c. on the 15th of February. At that time I attempted to control his blood sugar by huge doses of iletin, for which he came to the clinic, and as much as from 100 to 118 units were given him daily with no reaction. His diet was greatly reduced but his blood sugar curve was not affected as the chart shows (Chart VIII). The patient grew discouraged and gave up his struggle, began to eat everything, and died on March 18th.

CASE VII.—A colored undertaker, thirty-two years of age, with no familial history of diabetes. He had been married nine years and had two children living and well. He had had measles, mumps, whooping cough, chickenpox, grippe, pleurisy and gonorrhea. Sugar had been found in his urine eighteen months before when he had applied for life insurance. He had had frequency of urination for the past eight or nine years. His weight had remained practically unchanged. He had always been fond of sweets but had discontinued eating them when sugar was discovered in his urine. He felt well and worked hard. Physical examination showed a robust young man with no abnormal physical findings. Upon admission his blood sugar was 280 mg. to 100 c. c. A glucose tolerance test gave the following findings:

Mgm /100cc	Before administration of 100 gm. of glucose	half hour after	one hour after	two hours after	three hours after	four hours after

Chart IX gives full information regarding the treatment and the progress of this case. The patient made a rapid and uneventful recovery, and was discharged on a sufficient diet for him to continue his occupation.

CASE VIII.—A merchant, fifty-five years of age, with no familial history of diabetes and no history of any of the diseases of childhood, or of operations. He complained of constipation, which was getting

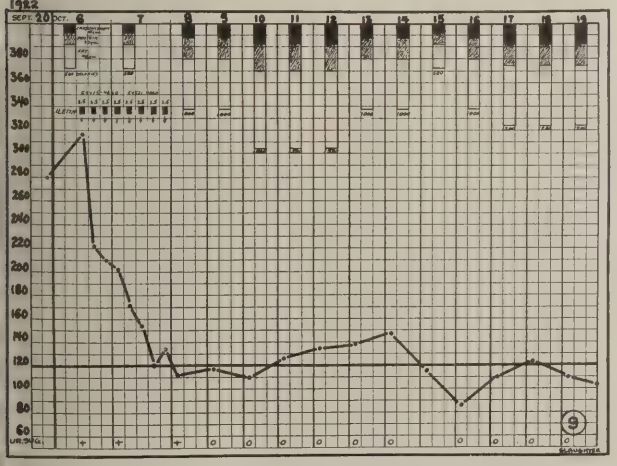

CHART IX.—Graphic record of treatment and patient's progress in Case VII.

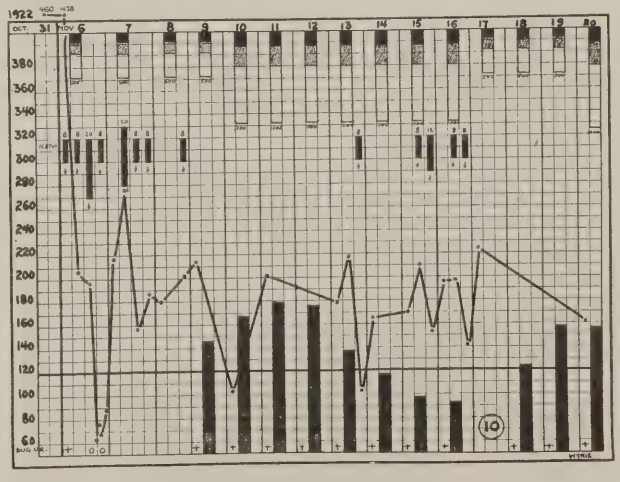

CHART X.—Showing progress under treatment of patient in Case VIII.

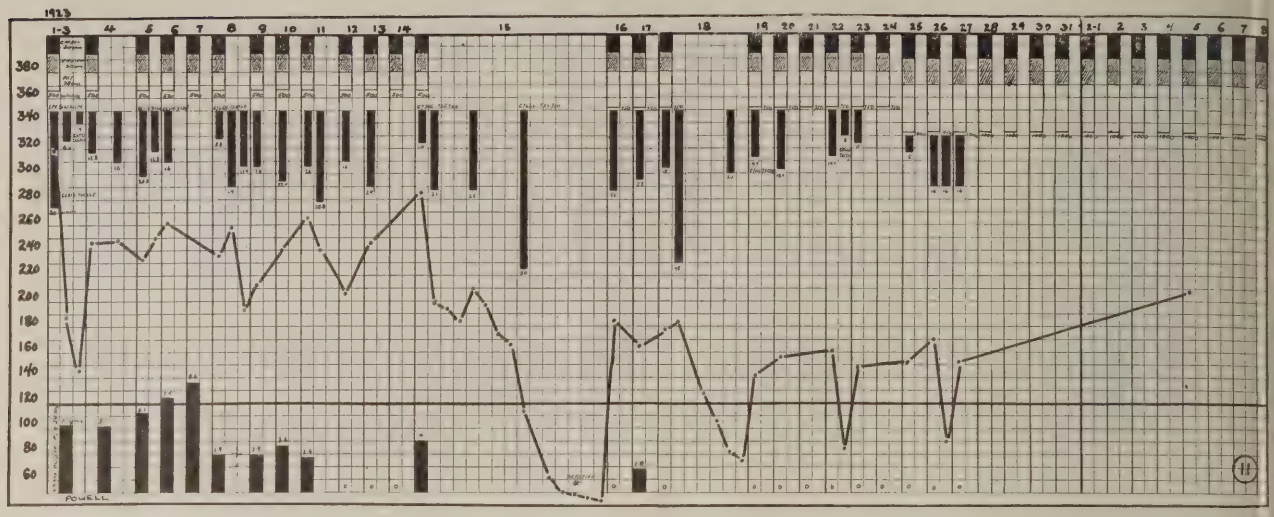

Chart XI.—Results of iletin administration in Case VIII.

continually worse. He had lost a good deal of weight; had a fair appetite but felt weak. He said he had no sense of feeling in his feet. The physical examination was negative. Laboratory tests showed sugar in the urine and blood sugar 460 mg. to 100 c. c. The Wassermann reaction was negative.

Chart X shows his progress under treatment. He received the first forty-four units of iletin in four doses, with a resultant abrupt fall of the blood sugar to below the normal level, and a reaction which, however, was not very severe. The following morning the blood sugar level was 276 mg. to 100 c. c., but with further doses of iletin it dropped to an average level of 170 mg. to 100 c. c. When the patient was discharged on the fourteenth day after he entered the hospital his blood sugar was 161 mg. to 100 c. c., he felt well, and most of his symptoms had subsided.

Case IX.—A factory workman, twenty-eight years of age, with no familial history of diabetes. He had had none of the diseases of childhood but had had lues and gonorrhea at the age of sixteen, for which he received antiluetic treatment. He complained of marked weakness and emaciation due to diabetes of five years' duration. During this time he had been on a diet; he had marked thirst and polyuria and had lost about thirty-five pounds in weight during these five years. Physical examination showed a rather emaciated young man, with dimness of vision, enlarged thyroid, and blood pressure—102-26. His blood sugar was 319 mg. to 100 c. c. and the urine contained acetone and 7.5 per cent. sugar.

The administration of iletin was begun at once, the results of which are shown on Chart XI. It will be noted that at first the patient was put on a low diet, namely thirty gm. carbohydrate, thirty gm. protein, a total of 500 calories. With this he received iletin two to three times daily, and although the doses were large, they did not make much of an impression on his blood sugar. Not until his fifteenth day in the hospital, when he received a total of 110 units of iletin, was I able to reduce the blood sugar. On that day it fell to the very low values of 61, 50, 49, 44 mg. to 100 c. c. respectively, and there was a very slight reaction. After these huge doses of iletin the blood sugar assumed a lower average level for a week, when the patient was discharged from the hospital. It would appear that in this case the heroic doses on the fifteenth day in some way helped to force the blood sugar level down and to keep it down, since up to that time doses of only fifteen to fifty units did not make much of an impression in spite of the low diet. The last blood sugar examination made June 15th showed a blood sugar content of 218 mg. to 100 c. c.

SUMMARY.

1. In a diabetic patient, varying periods of hyperglycemia follow each meal. Insulin seems to prevent this postprandial hyperglycemia and in some cases to induce a period of hypoglycemia after the ingestion of food.

2. The response to insulin apparently depends upon all of the factors which are concerned in the individual case. It would appear that a more prompt response follows the injection of insulin in cases in which the diabetes is of recent development although this statement must be considered as a generalization only.

3. Reactions to insulin, usually attributed to hypoglycemia, do not always vary in their intensity with the degree of hypoglycemia. These reactions sometimes occur when the blood sugar is within normal limits and sometimes even in the presence of a high blood sugar content. Often these reactions appear in from three to ten minutes after the intravenous injection of insulin. The period of onset, however, usually bears no definite relation to the blood sugar content.

4. The onset of a cold in the presence of diabetes causes an immediate rise of the blood sugar content which, especially in younger patients, tends to lower permanently the carbohydrate tolerance. This observation indicates that a cold may be considered as a definite causative factor of diabetes in patients in whom a prediabetic condition is present, that is, who have a lowered carbohydrate tolerance.

5. Whether or not in the individual case the injection of insulin is followed by a definite decrease in the blood sugar content, the general clinical improvement in these patients is marked. Increased experience will prove whether or not this apparent general improvement is due in part to psychic factors or to the insulin treatment *per se*.

A Rapid Simple Procedure for Estimating Small Amounts of Glucose in the Urine in Diabetic Cases, as a Guide to Insulin Therapy

JOHN R. WILLIAMS, M.D.,
and GERTRUDE U. CASEY, B.S.,
Rochester, N. Y.

The continued successful management of a case of diabetes mellitus under insulin therapy demands a recognition of three fundamental principles.

1. An approximate balance must be maintained between that fraction of glucose in the prescribed diet which the body cannot burn because of the diabetes, and the dose of insulin required for its utilization.

2. The diet must be of such a character and so distributed through the day as to permit of the greatest degree of utilization.

3. The dose of insulin must be of sufficient quantity and so distributed through the day as to care for ingested glucose.

If samples of urine of the diabetic under treatment be examined during the day, one of three conditions will be found.

1. The patient may be entirely sugar free, in which case the blood sugar is constantly below the kidney threshold point of elimination. In such a case the blood sugar will be found normal much of the day, a most satisfactory state.

2. Small amounts of sugar may be found in all of the voidings which will mean that the renal threshold is constantly being exceeded, that the blood sugar is constantly higher than normal and that improper balance exists between insulin doses and food intake.

3. Urine sugar may be found in one or more voidings, remaining specimens being clear. This means that during the glycosuria period the renal threshold is being exceeded and that readjustment of either diet or insulin therapy is necessary for those periods.

Clinical experience with insulin therapy in upwards of three hundred cases over a period of one and a half years shows that patients undergo change and frequently need readjustment of both dose and diet. Also that those patients do best in whom the diabetes is controlled.

It would be helpful if a simple method were available which could be used by the intelligent patient or the family doctor in readjusting diet and insulin dose. The following plan is employed by the writers with a degree of success which justifies its more general use. It is assumed that the patient is under treatment, that diet and the insulin dose have been carefully estimated and that the patient is at home under the observation of the family physician. Sugar is found in either a single or twenty-four hour specimen. The patient is then instructed to save each voiding separately in a clean fruit jar for twenty-four hours and a quantitative estimation of the sugar present is determined by a simple adaptation of the quantitative method first suggested by Benedict (1) and simplified by Joslin for the use of nurses (2). We have further simplified the procedure by using a special pipette made for us and by the use of a table of values which obviates some of the mathematical calculations. The method as simplified is well adapted for the estimation of small amounts of sugar such as is found during the day in the urine of diabetics under insulin treatment.

TABLE FOR DETERMINING PERCENTAGE OF SUGAR IN URINE (SIMPLIFIED BENEDICT'S METHOD*).

Urine		*Benedict's Reagent*	
No. of c.c. Urine	No. of minims Urine	Per cent 15 c.c. reagent (expressed in decimals)	Sugar using 25 c.c. reagent
(1)	(2)	(3)	(4)

14.00	227.	0.0021	0.0036
15.00	.....	0.0020	0.0033
16.00	.....	0.0019	0.0031
17.00	.....	0.0017	0.0029
18.00	.....	0.0016	0.0027
19.00	.....	0.0016	0.0026
20.00	.....	0.0015	0.0025

*This table is based on the fact that twenty-five c.c. Benedict solution is exactly reduced by 0.05 grams of glucose.

If a specimen of urine contains so much sugar that 24 min. or less of it is sufficient to reduce fifteen c.c. of the reagent, the specimen should be diluted with one or preferably two volumes of water, and the correction made accordingly. For instance, if diluted once, multiply by two; if diluted two times, multiply by three, etc. We recommend using fifteen c.c. of Benedict's quantitative solution and the minim scale as the unit of measurement. The table, however, is arranged so that the original Benedict technic may be employed, in which instance twenty-five c.c. of the reagent and the large dropping pipette, graduated in c.c. should be used. The latter procedure is to be preferred when a large volume of urine contains only a small amount of sugar. In case the number of minims or c.c. required for the total disappearance of the blue color is not shown in the table, the number nearest should be used. An example is as follows: A single specimen of urine of 350 c.c. volume is found by the Benedict quantitative method to contain sugar. The urine is then tested according to the foregoing plan: Using fifteen c.c. of the reagent, twenty-six min. of urine caused a complete disappearance of the blue color. Consulting the table it is noted that twenty-six min. (column 2) does not appear in the scale, and that twenty-four min. is the nearest number. In column 3, under "fifteen c.c. reagent," it will be noted that the amount of urine contains a little more than two per cent sugar, the exact factor being 0.0201. If the total volume of the urine, 350 c.c., be multiplied by 0.0201 the total number of grams of sugar in the specimen will be ascertained, which is a little more than seven grams.

As is well known, Benedict's quantitative method is based on the reduction of an alkaline copper solution, in which the blue reagent is converted into an insoluble white precipitate. The reaction is striking and the end point definite and easily determined. For the convenience of those who may not have the formula at hand it is given below. This solution keeps indefinitely.

	gm. or c.c.
Copper sulphate, pure crystallized.....	18.0
Sodium carbonate, crystallized (one half the weight of the anhydrous salt).....	200.0

	gm. or c.c.
Sodium or potassium citrate	200.0
Potassium sulphocyanate	125.0
Five per cent. potassium ferrocyanide solution	5.0
Distilled water to make a total volume of	1000.0

With the aid of heat dissolve the carbonate, citrate and sulphocyanate in enough water to make about 800 c.c. of the mixture, and filter if necessary. Dissolve the copper sulphate separately in about 100 c.c. of water and pour the solution slowly into the other liquid, with constant stirring. Add the ferrocyanide solution, cool and dilute to exactly one litre. Of the various constituents, the copper salt only need be weighed with exactness. Twenty-five c.c. of the reagent are reduced by fifty mg. of glucose.

The utensils needed for the test are: one 500 c. c. conical graduate; one asepto volumetric pipette graduated at 15 and 25 c. c.; one asepto volumetric pipette graduated both in tenths of a c. c. and minims, of 3 c. c. and 50 minims capacity; one casserole or enamel ware cup of about 175 c. c. capacity. Small

FIG. 1.—Apparatus used in carrying out simplified Benedict quantitative test.

quantities of sodium carbonate, calcium carbonate and talcum (Fig. 1).

It is advisable first to determine the presence of sugar in the urine by some qualitative method for which purpose Benedict's qualitative reagent is best suited. If sugar be found the amount may then be determined by means of the quantitative reagent as follows: The total volume of the urine specimen should be estimated in c. c., and a 500 c. c. conical graduate is recommended. Using the special 15 to 25 c. c. volumetric pipette, 15 c. c. of the Benedict solution should be put in the enamel cup with about one half teaspoonful of anhydrous sodium carbonate and one fourth teaspoonful of talcum, the latter to prevent the liquid when boiling from spurting. Benedict advises the use of 25 c. c. of the reagent in making the test, but we have found 15 c. c. sufficiently accurate for this purpose. The solution is then brought to boiling temperature on a gas stove or over a free flame for which purpose a sterno lamp may be used. From the 20 minim special pipette urine is dropped rapidly into the boiling solution until the blue color disappears and a white precipitate forms. The exact number of minims or c. c. of urine re-

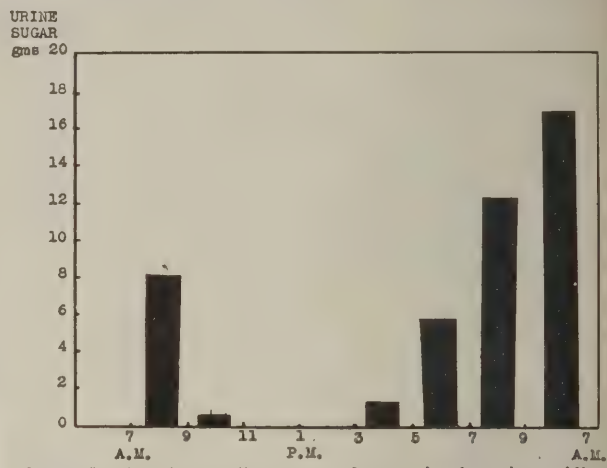

CHART I.—Showing small amounts of sugar in the urine voidings of a diabetic patient during twenty-four hours. This patient had a single daily dose of thirty units of insulin at 8:30 A. M. It served to keep his urine sugar free from 11:00 A. M. to 3:00 P. M. It will be noted that the various two hour samples and the night urine contained from one to sixteen grams of sugar. The thirty unit dose was then divided so that portions were given before each meal with distinct improvement in glucose utilization.

quired to complete the reaction is noted on the pipette. The percentage of sugar then may be easily determined by consulting the table (p. 237). The minim scale is used when small amounts of urine serve to reduce the copper, these graduations being finer and more easily and accurately read. If the mixture becomes too concentrated in making the test, hot water is added, being careful not to exceed the original volume. Some highly concentrated urines produce a brownish green color which is quite confusing and obscures the end point. Joslin overcomes this difficulty by adding calcium carbonate. We find that one half teaspoonful is sufficient to clarify the

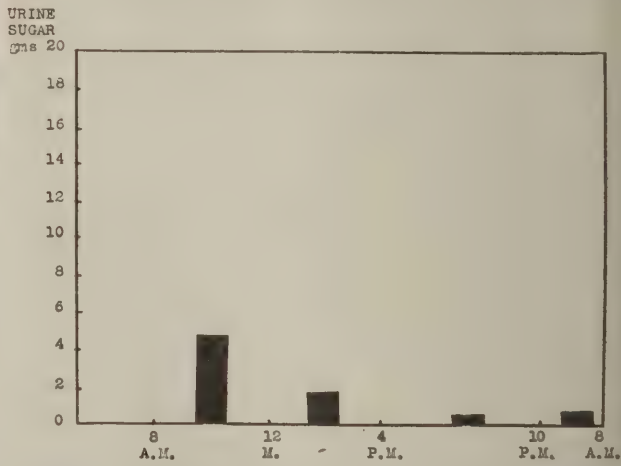

CHART II.—Showing small amounts of urine sugar in the various voidings of a diabetic patient during twenty-four hours. Severe case. This patient was receiving fifty-eight units of insulin daily. The morning dose of twenty-one units was taken at 9:00 A. M. This should be increased five units and given at least two hours earlier.

mixture of the greenish brown color. The test should be completed in from one and a half to three minutes.

A practical application of the test is as follows: If it is found that the patient is eliminating ten

grams of sugar at one period of the day, say at night, the diet for the evening meal may be reduced ten or more grams of glucose, or from three to five units of insulin may be added to the evening dose. If the diet be high and the patient in a state of good nutrition, the former procedure is followed, but if the diet be low and the patient undernourished, the additional insulin is added.

We call attention to a simple plan for estimating small amounts of urine sugar, using well known standard solutions. The method may be employed by either physician, nurse, or trained diabetic patient in regulating the diet and insulin dosage in cases in which the patient has been previously studied and the salient facts about his metabolism are understood.

Further Observations on the Relation of Teeth, Tonsils and Intestinal Toxemias to Diseases of the Eye*

GEORGE HUSTON BELL, M.D., F.A.C.S.,
New York,
Attending Ophthalmic Surgeon, New York Eye and Ear Infirmary and New York Polyclinic Medical School and Hospital

This is a fitting time and place to present another paper on this subject or what I call my Three T's. If the span of life is to be extended then education of the health must go forward with education of the mind. It was not until about ten or twelve years ago that any great attention was given to the fact that infections about the teeth could cause disease in other parts of the body. My first paper on the Eyes and Teeth was read in 1910 at the New York Academy of Medicine. Ever since then I have been hammering away at focal infections as a cause of systemic disease. In 1919 I presented my Three T's to the American Medical Association at Atlantic City. Every patient of mine, whether clinical, or private, must stand the acid test for the Three T's (teeth, tonsils and toxemias of the intestinal tract). If the physician or dentist has these Three T's well in mind constantly, there is no chance to overlook any of the great sources of focal infections. The ramifications of the Three T's are so interwoven that it is impossible for me to dissociate them. In thinking of one in connection with a patient, the other two always come into my mind—in other words, they go hand in hand.

This paper is a plea for a more thorough consideration of the Three T's and for what they stand. When we realize that ninety out of one hundred persons die of some secondary disease, the direct result of some focal infection, then I think the time is certainly ripe for a serious examination of every patient that comes to the office or clinic.

THE TEETH

My experience teaches me that in the mouth will be found evidence of more disease than in any other region of the body. That is the reason why I said at the meeting of the American Medical Association that a "dirty mouth is one of the greatest menaces to the human race." In 302 patients with disorders of the stomach seen at the Mayo Clinic, 253 suffered from pyorrhea. What are we going to do for dental caries and pyorrhea. The answer is the reform diet and oral hygiene. Dead teeth, dental caries and pyorrhea are arch enemies of the ophthalmic surgeon. I said at Boston before the American Medical Association that it was just as necessary for the ophthalmic surgeon to clean house before operating as it was for the general surgeon. I wish to lay great stress upon the extraction of all dead teeth, regardless of x ray findings, provided the patient has any obscure symptoms which cannot be explained.

I have the records of over one hundred cases of obscure eye diseases which have been cured by the extraction of dead teeth, dead roots and fixed bridges. In twenty per cent. of these cases the x ray findings were negative. A great many of these patients had four or five pictures taken before any extractions were undertaken. I insisted on the extraction of the negative dead teeth just the same.

In every case where the tooth was removed it was found under bacterial examination to be infected. I wish to state that I am unalterably opposed to dead teeth, dead roots and fixed bridges.

HAY FEVER CURED BY THE EXTRACTION OF A DEAD TOOTH

Case.—I will now cite one case from my practice (I could give you one hundred). This lady, aged fifty, came to see me for chronic conjunctivitis which she had had for ten years. She had been treated by several well known oculists here in the city. She had also been a sufferer from hay fever for ten years and had the usual red eyes which you see in hay fever cases. She had had conjunctivitis for so long that an ectropion of both lower lids was developing. This patient had had the usual astringent treatment for this disease, but was gradually getting worse. I refracted her carefully and changed her glasses by increasing her astigmatism against the rule, looking her over for the Three T's. Her tonsils had been removed; her mouth presented a fine set of teeth, except for one dead tooth. This was x rayed and found to be negative. I advised extraction of the dead tooth, to which she finally consented. On examination the tooth was found to be infected. An improvement in the condition of the eyes immediately set in. In three months there was absolutely

*Read before the National Life Extension Convention at Cincinnati, Ohio, January 7, 1924.

no trace of the ectropion, the redness of the eyes had disappeared and, strange to say, three years have elapsed with no recurrence of the hay fever. This is the fourth case of hay fever that I have seen cured by the removal of dead teeth, which had been pronounced negative and safe after x ray findings. I am fully persuaded that dead teeth will become a serious menace to the life of the individual sooner or later as I hold and believe that dead teeth will eventually pursue their natural course to putrefaction and infection. Much more could be said about oral sepsis as a cause of diseases of the eye and general systemic diseases, such as gastritis, arthritis, ulcers of the stomach, arteriosclerosis, insanity and diseases of the heart. I am constantly reminded that pyorrhea is rampant, filthy mouths, spongy gums and advanced oral sepsis are seen on all sides.

THE TONSILS

Next on our program come the tonsils. The rôle of the tonsils as foci of systemic infection has long been known, yet how often are they overlooked unless the physician has the Three T's well in mind. Inspection of the tonsils is not enough. A culture from the surface of the tonsils and inside the crypts is absolutely necessary. Because of their position and structure, the tonsils are more prone to infection than any other organ in the body. Because of their position, they come in contact with various species of bacteria found in the mouth. More important than this, however, is the deposition of these bacteria with food which we find in the lumina of the crypts. We must also bear in mind that constant swallowing of infected secretions of the mouth and tonsils, is one of the greatest sources of danger to the human race. The septic condition of the tonsils was well illustrated in the case of a physician, a friend of mine, who was operated upon and reported by King. The patient had arthritis, heart and kidney trouble with episcleritis. He was unable to attend to his professional duties. The whole systemic involvement was cleared up with enucleation of his tonsils.

I maintain that tonsillectomy confers a high degree of protection against acute streptococcic infection of the lymphoid tissue of the throat. Then, what is the sense in wasting time in treating diseased tonsils? I personally have examined over three thousand pairs of tonsils in the last six years, as I inspect every man, woman and child that comes to my office for diseased tonsils, and I have yet to find a pair of healthy tonsils. Then, what is the sense of dillydallying with diseased tonsils. The answer is enucleation.

TOXEMIAS OF THE GASTROINTESTINAL TRACT

We know now that gastrointestinal disturbances and severe septic intoxication are brought on or aggravated by oral sepsis, diseased tonsils, and wrong food combinations, and not infrequently by all three. What is the sense of putting patients on a diet unless you are going to get rid of infected teeth and diseased tonsils. There is a growing demand for a scientific supervision of the diet both in health and disease. Diet and health are conjoined from the cradle to the grave and should therefore receive the careful consideration of both physician and dentists. I want to emphasize the importance of using certified raw milk and of eating green vegetables, raw fruits and salads. We should consume one quart of raw milk each day, or its equivalent in dairy products. Raw fruits and raw foods should be eaten as desserts and salads once or twice daily to insure the required amount of vitamines. In the cooking of vegetables something essential is destroyed. We ought, each day, to eat freely of some leafy vegetables such as spinach, lettuce, Brussells sprouts, cabbage or beet tops. The consumption of these leafy foods will go far toward overcoming constipation.

I have a reform diet which I use in my practice and also in my clinics. The principle of this diet is simple and plain. The rule is not to eat heavy starches and heavy proteids at the same meal.

Heavy starches: Bread of all kinds, potatoes, macaroni, corn, lima beans, rice, dry beans, sugar.

Line A

Heavy proteids: Meats of all kinds, fish, shell fish, chicken, duck, turkey, eggs and cheese.

Nothing above Line A must be eaten at the same meal with anything below Line A. Heavy starches above Line A must be eaten with fresh vegetables and salads and fruits for dessert. Heavy proteids below Line A must be eaten with fresh vegetables and salads and fruit for dessert. I have a diet sheet which I will pass around to the members. Anyone who does not like my combinations can make up his own, as long as he does not violate the rule and principle of the reform diet. You may eat any kind of food you like or choose provided you eat it at the right time. It is the never ending fermentation in the stomach and putrefactive conditions in the intestines, brought on by wrong food combinations, bad teeth and diseased tonsils, that is destroying the human race.

My reason for separating the heavy starches and proteids is that there is nothing in the stomach to digest the starches. The starches are digested in the mouth and intestines and if they are detained in the stomach with proteid food, the starches ferment and fight with the proteins. So eat starches when they won't be delayed in the stomach. When meat is eaten it causes a flow of gastric juices. In discussing my reform diet at the New York Academy of Medicine, R. H. Rose hit the nail on the head when he said, "It has been long recognized that in hyperchlorhydria carbohydrate digestion is checked by hydrochloric acid—meat stimulates hydrochloric acid, therefore interferes with the digestion of carbohydrates. For that reason take heavy carbohydrates when heavy proteids are not eaten so that they can get out of the stomach immediately." I have known for a long time that most people eat too much and that the gastrointestinal tract is a storehouse for toxemia. That is the reason why I take up with every patient that comes to see me the question of the diet.

CHRONIC GLAUCOMA DUE TO THE THREE T'S

A few words about glaucoma, the cause of which is little understood. From my point of view, chronic glaucoma is the outcome in every instance of prolonged chronic autotoxemia, provided we can exclude syphilis. My experience teaches me that chronic constipation, gout, rheumatism, arteriosclerosis, uric acidemia, or all of them exists in those who become the victims of glaucoma. Gen-

erally the tongue is heavily coated, and the breath is foul. The odor of the breath is often a significant index of the blood conditions. When it is offensive, to me it is always suggestive of toxemia. I said at the New York Academy of Medicine eight years ago that fewer of our glaucoma cases would come to the operating table if we would only remove the focal infections and the profound toxemia from which these patients all suffer. I wish to stress the fact that glaucoma is not merely a local disease, therefore it must be treated constitutionally as well as locally and surgically. I have the records of over fifty cases of chronic glaucoma which I am treating according to my method. So far, none of these patients have yet come to the operating table. Some of them have been under observation for ten years. When a great authority on glaucoma, like Elliot, comes out in his latest book and says, "It seems probable that one of the greatest advances of the future in the treatment of glaucoma may lie in the direction of the early and scientific combating the sources of autointoxication"—then I think it is high time that all ophthalmologists "watch our step" in glaucoma cases.

Briefly, my method of treatment is as follows: First, get rid of all dead teeth, fixed bridges, and oral sepsis; second, enucleate the tonsils, if this has not already been done; third, take Wassermann blood test, and urine examination; fourth, take chemical blood test to ascertain if there is an excess of uric acid in the blood; fifth, reform diet and bacillus acidophilus milk internally; sixth, nitrate pilocarpine in the eyes locally two or three times daily. Hot applications to the eyes three times daily and a hot bath at bed time. In uveitis, iritis, iridocyclitis, keratitis and optic nuvitis, I use the general method described above, except different drops for the eyes. The exclusion of heavy meats, sugars and stimulants such as coffee, tea, alcohol and tobacco, are most essential in the treatment of diseased conditions of the eyes.

CONCLUSIONS

1. The day is at hand when the progressive ophthalmologist and dentist must take up with their patients the question of the diet.

2. We must remember that sugar, sweets and soft carbohydrates are among the causes of the modern increase in dental caries.

3. Do not forget that meat and bread and meat and potatoes when eaten together ferment in the stomach and produce poisonous gases and other products of acidity, which will finally destroy you.

4. The proper diet, which means the reform diet, on the part of the pregnant mother and the child, combined with oral hygiene, makes good teeth.

5. In all our cases syphilis and gonorrhea must be excluded and all patients must have their urine examined at least once a year.

6. If we want to put a check on the degenerative diseases of middle age, we must keep our eyes open and keep a sharp lookout for the Three T's.

7. The tragedy of delay in some of the focal infection cases that I see is simply appalling.

8. In the light of my experience, I feel that I cannot do better than to go on preaching the gospel of the Three T's.

40 East Forty-first Street.

Penetrating Injuries to the Eye in Industrial Occupations*

FRANK ALLPORT, M.D.,
Chicago

The eye may be penerated by steel, copper, wood, glass, etc., and the object drop out, be winked out, or be drawn out by a hand, etc., leaving behind it injuries that are more or less serious, and too numerous in character to be separately enumerated. The penetrating object may enter through the closed lid, cutting or not cutting the tarsus, or it may enter the eyeball direct, and either remain in the globe or come out of itself, or be removed by other agencies. Of course, those objects that penetrate the eyeball and come out without operative intervention are almost invariably long, spindling foreign bodies, too long in fact to enter the ball and be concealed within its walls. The treatment consists in the removal of the invader (if it has not already been done), antiseptic cleansing, and the care of conditions as we find them, remembering that hardly any two of such accidents will be exactly alike. We may find perforation of the sclera or cornea, prolapse of the iris, cataract, intraocular hemorrhage, etc., all of which conditions must be cared for in the manner understood by experienced ophthalmic surgeons. Such conditions may also exist if the foreign body is small in size, and has not only penetrated the eyeball but has also remained inside its walls.

I may as well say at the outset that I believe all cases of invasion of the eyeball by a foreign body should be submitted to an experienced x ray practitioner. The presence or absence of a foreign body should be positively known, as well as its size, shape and location. Only good and clear pictures should be accepted, as very much depends on their verdict, and I have known poor pictures to be shamed by good pictures, which disclosed the presence of a foreign body—undiscovered by the former. I require a front view and a side view, and, after I have seen and studied these, I do not as a rule feel the necessity of further localization. I say nothing against localization, and in some few cases it is most desirable, even a necessity. I refer particularly to those cases where it is questionable whether the particle has gone clear through the eyeball, and is outside of the sclera, perhaps in the cellular tissue of the socket. The knowledge of such a position is evidently of extreme value, for, as a rule, such cases are best let alone, so far as magnet or other withdrawal is

*Read before the Chicago Society of Industrial Surgeons, January 8, 1923.

concerned, unless the piece is of such large size as to render it dangerous to leave alone; in which case the severance of one of the lateral recti muscles, the pulling forward of the eyeball, the removal of the foreign body by forceps, etc., the replacing of the parts, etc., or the performance of the Kronlein operation must be taken into consideration. In some cases, where there is a doubt as to whether the particle is in the lens or not, exact localization is of value, but, as a rule, if I can have good clear side and front x ray pictures, I feel satisfied to proceed with my operation. I believe that practically all that is really essential to know is, in which quadrant of the globe the foreign body is located. With this knowledge in hand, the exact line for line location of the particle is unnecessary. The interior of the globe is not a vast chamber at the worst, and a strong magnet introduced at either desired quadrant should be able to withdraw a piece of steel without difficulty, unless it is tightly buried in the sclera, under which circumstances we might have difficulty in acquiring success, even with exact localization.

Of course there are other foreign bodies that invade the eye besides iron and steel, and these are particularly unfortunate cases. As magnetic attraction has no influence over wood, copper, glass, etc., they are almost hopeless. Exact localization is important, as the foreign body will have to be removed with forceps. The pupil should be dilated, as the operator must work with ophthalmoscopic observation, provided the invader is in the vitreous chamber. I have from time to time removed such particles, located in the anterior chamber or lens, through the cornea with success, but have invariably failed in saving the eye where I have entered the vitreous chamber through the sclera. I have, I think, twice removed the foreign body, but in every instance the eye has been lost, although I note some success in other operators' reports. I believe, however, that the attempt should be made, and I presume that some successes will be attained. I believe that a very small pair of Noyes's alligator nasal forceps is the best instrument for withdrawing the foreign body. They open only at the end and, therefore, no traction is made on the scleral wound. Of course, of all substances glass is the most difficult to see, either with the x ray or otherwise. It would also be the most difficult to withdraw, but, fortunately, its presence inside the eye must be extremely rare, for, in a rather large experience in injury cases, I have never seen even one instance of such an accident.

The subject of foreign bodies inside the eyeball practically resolves itself into a consideration of steel or iron particles. Fortunately such particles are removable with the magnet, with the single exception of manganese iron fragments, and these are rare.

Much has been written on this subject, and diverse views are entertained by competent and honest surgeons. I feel constrained to give my own views, leaving it with operators to choose between my methods and the methods of others. I am not willing to adopt the dictum of Haab and others, that practically all foreign bodies should be removed through the cornea. In the first place, there are but few genuine, powerful Haab magnets in this country, and it sometimes requires enormous magnetic attraction to pull a piece of steel from its firm bed in the posterior sclera to the anterior chamber. Besides this, I cannot believe it a good plan to pull a good-sized, jagged piece of steel through the lens, iris, ciliary processes, etc., in order to deliver it through the cornea. Of course, Haab lays out a most attractive itinerary, or route, for the removal of the steel, by which it may be delivered into the hands of its captor, without much damage to the eye. The steel (according to Haab) is to be coaxed along the floor of the vitreous chamber, and to be very softly carried over the sensitive ciliary processes. It should then pass through the circular ligament of the lens without doing any particular damage, and then be lifted over the wall of the iris, over the pupillary opening, and then dropped on to the floor of the anterior chamber, from whence it can be extracted by a corneal incision and the magnet. This sounds almost like a fairy tale. It can be practically done by an expert, if the object is very small and comparatively smooth. In my opinion, it cannot be done, even by an expert, if the object is large and sharp. What usually happens is, that the powerful magnet is approached to the eye, when suddenly the object presents itself against, and sometimes through the cornea, carrying with it various portions of the internal anatomy of the eye. I believe that in recent injuries where the cornea is still open, and where the lens is already cataractous, the foreign body may quite properly be withdrawn through the original opening, which may have to be somewhat enlarged, but, where the corneal wound has healed, and especially where no cataract is present, the posterior or scleral route should be utilized for operation. I have laid down the rule that the corneal or anterior route should only be used where the foreign body is in or anterior to the lens. All other particles should be withdrawn through the posterior or scleral route.

Some surgeons believe that if the foreign body is in the lens, it should be left alone, as the lens has no sensory nerves, and the case is practically safe. In this view I do not agree. Such cases sooner or later come to grief, and I believe it is wiser to remove all intraocular foreign bodies, wherever located, as soon as possible, provided it can be done without almost irretrievable disaster to the eye itself. Fortunately, many pieces of steel that enter the eye come fresh from the fire and are aseptic, or they are rendered aseptic by heat derived from the friction of a hammer blow or the rapid propulsion through the air. Nevertheless, they should be removed as speedily as possible.

If the foreign body is located in or anterior to the lens, it can usually be removed by the magnet through a corneal opening of appropriate size. I believe, if it is in the lens, and does not come out readily, it is better to wait a few days—until irritation has subsided, and then make a conventional cataract operation, removing both lens and foreign body. Care should be taken that the foreign body is actually removed, to which end, the magnet, anterior chamber flushing, etc., may be necessary. I believe the results are better in such cases if the lens removal is preceded by an iridectomy. I believe that a serious mistake is frequently made in operating on traumatic cataracts, in assuming that a small

keratome opening is sufficient to afford free exit for the lens matter. Such lenses are seldom as liquid as we are led to expect. Many of them are quite substantial and cannot escape except through a fairly large opening. A cataract incision, whether for a senile or a traumatic cataract, should be ample, to avoid vitreous escape, or enlargement of the wound with scissors, both of which always lessens the percentage chance of a good recovery. Besides this, in almost all such cases, the anterior chamber irrigator will have to be used to flush away all possible lens material, in order to lessen the chances of an iritis. For this purpose a fairly large opening is necessary, not of course as large as for a senile cataract, but fairly large. A Graefe cataract knife may be used, or a large keratome, although the latter requires more force than a Graefe knife. Fisher's retractors are better than a speculum, for they lessen the liability to lose vitreous. Very little pressure on the eyeball should be used by spoons, etc., for in these traumatic cases the hyaline membrane and posterior capsule are usually broken and the vitreous escapes easily. If considerable vitreous is lost, its place should be supplied by the injection into the posterior chamber of enough warm normal salt solution to fill out the globe.

If the foreign body is in or anterior to the lens, it is frequently easy to hold the magnet to the eye, before a corneal incision is made, and attract the object to the floor of the anterior chamber, from whence it can be easily extracted by an incision made at the very bottom of the chamber and the magnet. If the incision is made above the floor of the chamber, the intervening corneal wall may prove quite an embarrassing obstruction for the magnet extraction. The foreign body may pull iritic tissue with it in process of its exit. If the iris is easily replaced, and stays replaced, it may be well to leave it, but, if it proves obstinate, an iridectomy had better be made. If the lens is broken down and soft, the opening should be large enough to facilitate lens removal by pressure, spoons, anterior chamber flushings, etc., in order to forestall, if possible, lenticular swelling, iritis, etc. The removal of intraocular foreign bodies is very interesting work. Each case must be judged by itself, and no hard and fast rules can be laid down for the management of all cases.

Let us now consider those cases where the foreign body is in the posterior chamber. The point of entrance may be through the cornea, sclera, or sclerocorneal junction. If it enters through the cornea, all sorts of corneal, iritic or lenticular damages may be present and each case must be judged by itself and treated accordingly. I have elsewhere recorded, and wish to record again, that I have seen one or two where minute steel fragments have passed clear through the cornea and lens without leaving any evidences of cataract behind. This seems well nigh impossible, but it is true nevertheless. One case, I remember distinctly, where a minute particle passed directly through the lens, leaving a minute track behind. This track subsequently cleared up, and a perfectly clear lens resulted. If the point of entrance is through the sclerocorneal junction, the damage may be similar, but it must not be forgotten that this particular territory is the most sensitive in the eye, and that injuries here are especially apt to produce sympathetic ophthalmia and protracted and unsatisfactory recoveries. I wish to say, however, that while I do not deny the existence of sympathetic ophthalmia, and have the greatest dread and respect for it, nevertheless I can truthfully say that, after a long and active experience, I am sure I have never seen six of these cases. So I cannot be blamed for feeling that the prevalence of this dreadful disease has been greatly overestimated. If the foreign body enters through the sclera, it frequently happens that little damage is done, and certainly, as a rule, there are few external evidences of trouble. A scleral wound and a soft eyeball are perhaps all the visible pathology present. Of course, in some cases of steel invasion, no matter where the point of entrance occurs, such profound trauma is produced that it is immediately evident that the case is hopeless from the start. Under these conditions enucleation should be advised at once; thus saving time, money, and shattered hopes, protracted illness, and semiinvalidism, to say nothing of the possibility of sympathetic ophthalmia. Frequently patients will not consent to such prompt surgery, but the advice should be recorded in writing, which may become useful in the future, for it must be remembered that all such patients are potential plaintiffs in legal proceedings.

After a foreign body has entered the eyeball a thorough examination of the eye should be made. The pupil should be enlarged, and the anterior portion of the eye examined under illuminated magnification. If possible, the anterior of the eye should be carefully observed with the ophthalmoscope, the x ray, and possibly localization should be employed. I do not, as a rule, believe in what might be called magnet diagnosis, that is, the approach to the eye of the strong magnet to see if the steel shows itself, or if the patient experiences any pain. Complications are likely to occur, under such a means of investigation, that will greatly embarrass the surgeon, and lessen the patient's chance of obtaining a good eye. The magnet should not be used until all the evidence is in and the plan of campaign understood.

We should be guided by our x ray pictures when the eye is opened. I am, of course, now speaking of operations through the scleral or posterior route. The incision should be between the superior and external, the external and inferior, the inferior and internal, or the internal and superior recti muscles; in other words, in one of the four quadrants of the eye, indicated by the x ray as the quadrant nearest the location of the foreign body. I pick up the conjunctiva, after local cocainization, near the sclerocorneal junction with forceps, and cut the apex of the conjunctival fold with scissors. I make a slender triangular flap, way back to the *cul de sac*. I close and spread the scissors beneath the flap, so as to thoroughly dissect the conjunctiva from the sclera. I lay back the flap, and I then plunge a Graefe cataract knife through the sclera, far enough back to avoid cutting the ciliary processes. This incision is enlarged backward, at an angle of about 45°, for nearly half an inch, in order to provide plenty of room for surgical procedures and for the withdrawal of the foreign body. If the latter is large, it may be necessary to enlarge the opening with scissors. If the

entrance of the foreign body has made a scleral opening, that is still open, it is often wise to utilize this opening, and enlarge it for the operative procedures. After the opening is ready the magnet—with its strongest point—should be placed in the open wound. I have devised two little nonmagnetic hooks that I place—one in each side of the wound—to open it. They seem to facilitate the withdrawal of the foreign body and are held by an assistant.

It is needless to say that all instruments used in this operation should be nonmagnetic. The point of the magnet should be aimed, as near as possible, at the long axis of the foreign body, as shown in the x ray pictures, for objects are much more readily and harmlessly removed in this way than if the magnet is aimed broadside at the object. We must from time to time be sure the magnet is working, by holding perhaps a pair of scissors toward it to see if the current is on full strength. I have seen failures occur from neglecting this precaution. Sometimes the foreign body fails to present itself at once; it may be stuck in the sclera, or covered with exudate. The current should then be switched on and off, on and off, etc., in order to jerk it loose. It may be well to give the patient a rest occasionally, and remove the speculum from the eye, and then go at it again. If, after giving the case a prolonged trial and no foreign body is removed, we shall have to consider the advisability of introducing a magnetic point inside of the eyeball, as close to the location of the foreign body as we can judge. This is a procedure that some surgeons do readily and more or less fearlessly. I cannot agree with this point of view. I regard the introduction of a magnetic point inside the eyeball as an exceedingly hazardous procedure, only to be done as a last resort, and after all other methods have failed. If, however, it becomes necessary, it should be done with exceeding gentleness and care, and for not more than (let us say) three times. The current should, of course, be on in full force when the point is withdrawn, as otherwise the foreign body might be stripped off at the moment of withdrawal. I have removed some foreign bodies in this way, when other means had failed, but I always felt I was indulging in a dangerous practice.

Occasionally more than one piece of steel will come away. Whether a plurality of pieces entered at the initial entrance, or whether a single piece has broken up into several pieces after entrance, I cannot say, but I believe in the latter view. If we do not succeed in withdrawing the foreign body easily, we should patiently persevere until success or failure is assured. I have sometimes found, in obstinate cases, that the foreign body can be moved by placing the strongest point of the magnet as far into the conjunctival *cul de sac* as possible, at the point where the x ray has located the foreign body, and then gently and slowly move the magnet down to the scleral opening, milking the eye, as it were. This can be done several times, in different locations, and should always be done before a magnet point is introduced inside the eye. I believe that more strenuous methods of procedure, other than those I have indicated in this paper, are unwarranted, and would result in the loss of the eye, almost without exception. I am not unaware of the dangers of removing foreign bodies through the scleral route.

After the foreign body is removed, or we are resigned to failure, the wound is closed. Do not stitch the sclera; it is unnecessary, and, as the sclera is thick and tough, considerable pressure is used in getting a needle through both lips of the incision, and vitreous may be lost. Besides this, part of a suture would of course be left in the vitreous chamber, which would invite intraocular infection if left (as with a catgut suture), or if removed (as with a silk suture), stitching the conjunctiva is sufficient. The apex of the conjunctival flap is so near the sclerocorneal junction that there is not enough conjunctiva to retain a suture. I, therefore, draw the flap forward, and suture the conjunctival triangular and tongueshaped flap to the conjunctiva left on the eyeball, one suture above and one below. This will be quite sufficient. I use fine silk sutures. The recovery after the operation is usually uneventful. The sutures may be removed on the third or fourth day. Of course, some of these cases speedily go to the bad, through iritis, panophthalmitis, etc., and enucleation becomes necessary. Others apparently do well for weeks or months, and then atrophy of the globe, intraocular pathologies, etc., occur, and the eye becomes useless, and may have to be removed. Sometimes the eye is permanently saved, with more or less vision. I have learned to maintain a guarded prognosis until about a year has elapsed. If then the result is good I feel optimistic, but not until then. The trauma and insult to the eye are great where a piece of steel has passed into perhaps the vitreous chamber. It is still more so when the steel is removed by a magnet, and still more so when perhaps further operations, like a cataract or an iridectomy, have to be performed.

The question as to what magnet is used is one that most surgeons view from the standpoint of their own experience. The genuine double ended Haab magnets are very expensive and scarce in this country. They are the most powerful magnets made, and perhaps the best for general use, although, when a magnet point is to be introduced inside the eye, I think some strong hand magnet—like Sweet's—is the best, as it can be more easily and delicately handled. Several substitutes for the Haab magnet have been introduced in America. Heavy magnets are best regarded as stationary instruments. In other words, the patient should sit and approach the instrument, whereas, in using hand magnets, the patient lies on the table and is approached by the instrument. I think on the whole that better work can be done by using a very strong hand magnet, such as Sweet's or Lancaster's, that combine power with flexibility, than by using a fixed magnet such as Haab's. I have used Sweet's instrument for years, and have been well satisfied with it. The chief objection to it is, that it quickly becomes almost, if not quite, too hot to handle. I have covered it with an asbestos overcoat, but the heavy magnet slips in the covering and interferes with the accuracy of its use. I have had no experience with the ring magnet, and therefore can say nothing about it. It undoubtedly possesses great power, that can be graduated to conform with the necessities of the case, and the handles can be easily manipulated.

7 West Madison Street.

Some Problems in Gallbladder Disease; Their Operative Treatment and Complications*

MOSES BEHREND, M.D.
Philadelphia

The differential diagnosis of gallbladder disease from other affections in the upper abdomen is at all times an extremely difficult and absorbing problem both for the surgeon and the internist. It is plainly obvious that a colic in the right hypochondriac region followed by jaundice points to some disturbance in the bile passageways. But when these symptoms simulate the pain of a duodenal or gastric ulcer, a high appendix, or even a stone in the kidney, the rendering of an exact diagnosis becomes increasingly difficult. To associate disease of the gallbladder or the bile passages always with stout individuals past forty, usually good livers, is a fallacy which must not be adhered to very closely, as illustrated by a patient recently operated upon. A woman weighing about two hundred pounds had symptoms resembling attacks of gallstone colic, which persisted for six years. The pain was severe, compelling hypodermics of morphine; at operation we found a pyloroduodenal ulcer of the hard, chronic indurated type, the socalled cured ulcer of the internist.

Cholelithiasis may be found in lean individuals which fact at times adds more difficulties in differentiating between gallbladder disease and pyloric or duodenal ulcers, because in these patients one would expect to find a lesion of the stomach or duodenum. Again a high appendix and gallbladder disease are often taken one for the other. It is at times impossible to differentiate between the two affections until the patient has been anesthetized. Such a case is illustrated in that of a man sent to the hospital with the signs of acute appendicitis. He had been sick several days with pain in the right side of the abdomen a little higher than it is customary to find a diseased appendix. The entire right side of the abdomen was rigid, and not until he was under ether could a large swollen definitely defined gallbladder be outlined. When the abdomen was opened a large hydrops of the gallbladder was revealed. Again a perplexing trilogy of diseases presents itself when it is necessary to differentiate between renal colic, gallstone colic and a high appendix. In gallstone colic the history of the patient may be helpful to a diagnosis when he has had symptoms of a long standing indigestion. In renal colic there are certain urinary reflex pains. However, the physical examination must assist materially in the diagnosis. In gallbladder disease tenderness is found under and just below the costal border; in renal colic the point of greatest tenderness is in the loin space, while many cases arise where it is absolutely impossible to make a differential diagnosis between a high appendix and gallbladder disease.

FOCAL INFECTION

The bile passages, especially the gallbladder, have been found a factor responsible for producing certain myocardial changes and longcontinued disturbances in the temperature balance of the patient. In addition to a prolonged temperature of undetermined cause the diseased gallbladder has given rise to a condition known as an extrasystole of the heart. Extrasystole in some patients is benefited and at times it disappears after the removal of an infected gallbladder. The accompanying cardiograms, Figs. 1, 2 and 3, and histories of two of the patients, were prepared by our cardiographer at the Mt. Sinai Hospital, Dr. Joseph Wolffe. They show definitely the presence of an extra beat which after operation was greatly improved and then gradually disappeared. The patient in case I was admitted to the Mt. Sinai Hospital November 11, 1922. For fourteen months prior to admission the patient noticed that after the ingestion of a rich carbohydrate meal he would have symptoms of epigastric and hypochondriac distress. He also became conscious of premature contractions of the heart. A cholecystectomy was performed; in addition a duodenal ulcer was removed with the cautery and inverted, after which a posterior gastroenterostomy was performed. Numerous subsequent examinations failed to show any evidence of disturbance of cardiac conductivity. The patient in case II was admitted on February 11, 1923. She had many reflex gallbladder symptoms following an attack of typhoid fever twenty years ago. During the last four years she had been conscious of some precordial disturbance. Cholecystectomy was performed, the gallbladder containing many small stones and viscid dark colored bile. The premature contractions disappeared quickly after the removal of the infected gallbladder. The third patient was operated on for Dr. Stambul. The patient was only temporarily relieved by operation. The gallstone attacks started during pregnancy and became especially annoying after labor. There was no question about the immediate improvement in the rhythm of the heart following operation and for four weeks thereafter. It is now stated by her physician that the irregularity has returned.

GLYCOSURIA AND INSULIN

There seems to be a definite relation between gallbladder disease and glycosuria. Many cases could be cited in which a secondary pancreatitis following gallbladder disease caused a definite diabetic state. While the presence of sugar in the urine is no contraindication to operation, there is unquestionably a greater risk in operating on these patients. The preoperative preparation of these patients has always been attended with the maximum amount of care. With the discovery of insulin greater security in operating on these patients can be realized. What a relief to the surgeon to know before operating that these patients are sugar free. While a ketonuria is an additional operating complication one feels more secure when the sugar in the blood and urine is re-

*Read before The Lake Keuka Medical and Surgical Association, Penn Yan, N. Y., July 26-27, 1923.

duced to a small percentage. Probably due to a coincidence the existence of glycosuria has been in many instances accompanied by chronic jaundice due to a stone in the common duct, a hardened head of the pancreas, or to a malignant growth at the papilla of Vater. We can report most gratifying results in those patients with glycosuria who have been prepared with insulin before operation. In a few instances patients who have been operated on have shown no trace of sugar, others have been temporarily relieved, while still others showed no improvement at all.

PROPER METHOD OF PERFORMING CHOLECYSTECTOMY

There are several methods of performing a cholecystectomy which may accomplish the same end but there is a logical method by means of which the operation can be better performed with the least consumption of time. As a result of the examination of nearly five hundred anatomical specimens in the Baugh Institute of Anatomy of the Jefferson Medical College a technic has been developed which in our estimation we consider almost perfect. From a close study of the anatomical relations the removal of the gallbladder from below upward is unquestionably the method of choice. As illustrated in a previous paper the right free border of the gastrohepatic omentum has been opened and a free wide dissection of the ducts and bloodvessels has been made; the cystic duct and cystic artery are clamped separately and divided. When we have removed the gallbladder from above downwards there has not been the same sense of satisfaction as when employing the reverse method.

DRAINAGE

Under drainage we wish first of all to discuss the material used for the ligation of the cystic duct. For years we have used catgut; during the past few months, however, we have been using silk or linen thread on account of a few leakages we had following the use of catgut. Since the adoption of this method there has been no trouble from this source. Catgut is still used in the ligation of the cystic artery. On account of the instability of the ligature material and the possibility of the slipping of a ligature and oozing which must necessarily follow the separation of the gallbladder from its bed we still place a small rubber drainage tube to the site of operation. This tube is allowed to remain five days. It has been our experience that even with the drainage a subhepatic or subphrenic collection may arise after its removal. We can only conjecture what happens in those cases where no drainage has been employed by the surgeon. The symptoms of a subphrenic collection are of much importance and the failure to recognize its existence may cause a fatal termination.

SUBPHRENIC AND SUBHEPATIC COLLECTIONS

In every subphrenic collection following an operation for an upper abdominal condition pain in the shoulder is the constant symptom. Pain in the shoulder is so striking a symptom that we may well call it a pathognomonic sign. It may arise suddenly after operation or there may be entire comfort after operation for several days, a week or more before the symptoms of a collection in the subphrenic space present themselves. The pain varies greatly in degree depending as it does on the amount of the collection, as well as the kind of the infection. It is generally of an excruciating character radiating to the right or left shoulder. Recessions in pain occur but usually it is constant and always worse at night. The expression of the face is characteristic; it is anxious, the eyes are somewhat protruding, glassy, and the patient's whole countenance beseeches one to do something to relieve him of his distress. Respiration is rapid necessitating the patient to sit up in bed. Physical examination will reveal an increase in liver dullness if the collection is confined to the right side, the increase being rather more lateral than medial. On palpation there is an increase in the resistance over the ribs; the hypochondriac region feels fuller as compared with the other side. If much fluid be present the costal border is fused with the surface of the abdominal wall. The excursion on the affected side is limited. The best method to find the exact location of the fluid is by means of the exploratory needle and the x ray, preferably the former. Wherever found a free incision should be made; if located high up it may be necessary to resect a piece of the rib.

Since I published my papers on the anatomical variations in the arrangement of the bile passageways and bloodvessels it has been interesting to note the universal approval of surgeons of this type of work. It has been especially gratifying because it tends to better surgery where so much poor work has been done in the past. The surgeon should possess a knowledge of the anomalies of construction so that when these abnormal conditions are found an intelligent understanding of the field of operation will assist much in the conclusion of the case. An interesting fact has been the comparison of findings in the anatomical laboratory with those found at the operating table. It is now a well known fact that twenty-five per cent. of the cases operated on show some anomalous arrangement of the bile ducts and bloodvessels. The same relationship holds good in the anatomical laboratory. While operating by the open method it is gratifying to be able to recognize the abnormal relations of bile passages and their bloodvessels. Naturally the arrangement most frequently found is the normal relation of the cystic duct ventral and dorsal to the artery, the hepatic artery in close relation to the cystic duct, the cystic artery of great length and caudal to the duct, a rather unusual arrangement, the cystic duct running parallel to the cystic artery, both being quite long, and many other variations.

OBSTRUCTION OF THE COMMON DUCT DUE TO INJURY AND DISEASE

Naturally the caution referred to in previous paragraphs as to the type of operation and the importance of the anatomical studies was for the purpose of eliminating altogether the injuries to the common duct which have been so frequent but which have not been reported as fully as they should have been. Obstruction of the common duct whether due to injury or disease is a serious matter on account of the chronic jaundice which accompanies this condition with its consequent degeneration of the vital organs. Many operations have been devised for the relief of this condition but for the description of its

technic I must refer you to special papers on this subject.

Suffice it to say there are two advocates of the treatment of obstruction of the common duct due to disease, some favoring internal drainage and others external drainage. I mention external drainage merely to condemn it, but there is a wide field of usefulness for internal drainage, the anastomosis, in other words, of the gallbladder and its passageways to the stomach or duodenum. I must repeat what I have said in the past that it does not make any difference whether the stomach or duodenum is used, the ultimate result will be the same, the stomach being tolerant to the presence of bile. In a case just operated on a few days ago for carcinoma of the papilla of Vater and the head of the pancreas the gallbladder was anastomosed to the stomach. There was no vomiting or other gastric distress afterwards.

PREOPERATIVE PREPARATION

The preparation of patients who have chronic jaundice on account of obstruction of the common duct due to injury or disease is of the greatest importance. These cases should have a complete blood chemistry, urinary examination, blood pressure, blood count and coagulation time taken. At least forty-eight hours before operation the patient should receive calcium lactate by mouth or calcium chloride intravenously; he should be digitalized and receive one thousand c. c. of salt solution by hypodermoclisis. After operation the digitalis should be continued and another one thousand c. c. should be administered. A blood transfusion should be given before and after operation when the hemoglobin is low or when the blood coagulation time is much prolonged.

EXPERIMENTAL WORK

We have checked up our work by experiments some of which are as yet unpublished. Especial attention has been given the accidental ligation of the hepatic artery and its dire results following its ligation. It has been definitely proven by us and others that a necrosis and degeneration of the hepatic cells result if the hepatic artery is ligated instead of the cystic. No mistake of this kind ought ever occur if precautions are used in the performance of a cholecystectomy by means of the open method. Ligation of the structures around the foramen of Winslow within the folds of the gastrohepatic omentum belongs to the surgery of the middle ages. Performance of the operation in this way accounts for many of the cases of destruction of the common duct.

CONCLUSIONS

In conclusion I wish to urge:

1. The importance of making a differential diagnosis between cholelithiasis, nephrolithiasis, a gastric or duodenal ulcer and appendicitis.

2. The importance of the gallbladder as a focus of infection.

3. The importance of the preoperative preparation of diabetic patients by means of insulin in cases suffering from disease of the bile passageways.

4. The importance of performing a cholecystectomy by the open method so that every structure can be visualized.

5. The importance of drainage in all cases of cholecystectomy after operation on account of the danger of a subhepatic or subphrenic collection.

6. The importance of possessing a profound knowledge of the anatomical relation of the bile ducts and bloodvessels. Only by this means is it possible to eliminate all injuries to the common duct.

7. It is always desirable to check up our work by means of experimental work on animals. In this way many surgical problems can be made clear.

Drowsiness

J. A. KEARNEY, M.D.,
New York

Professor of Ophthalmology New York Polyclinic Medical School and Hospital; Visiting Ophthalmologist Bellevue and Allied Hospitals—Gouverneur Division.

Drowsiness is one of the annoying symptoms often noted in a routine ophthalmological practice. Affections of the conjunctiva and marked reduction of vision in both eyes are usually the accompanying ocular conditions observed that account for this complaint. An existing uncorrected error of refraction *per se* is seldom found to be a factor in its production.

After eliminating present and past constitutional dyscrasias that may account for drowsiness, the problem is reduced to a solution of possible ocular factors contributing to it.

An unpolished or uneven surface of the palpebral conjunctiva is found to be the chief source of drowsiness, although the low grade catarrhal affections of this membrane are observed most frequently. The low grade catarrhal affections producing drowsiness seldom present any external evidence of disease, but by everting the lids, the conjunctiva appears dryer and redder than normal and upon close inspection the surface is studded with minute fine points. Occasionally, a low grade catarrhal affection of the palpebral conjunctiva has extended to the margins of the lids and by viewing the eyes externally, the margins appear redder than normal; a history of small hard crusts found at the inner canthi in the morning is usual when this condition obtains. Drowsiness usually disappears when the affected conjunctiva is polished by a course of treatments. Many patients who consult the ophthalmologist first hand attribute their drowsiness to eyestrain and feel that correcting glasses will remedy the trouble, but it is surprising to note how few of such patients who complain of drowsiness of itself have any error of refraction when estimated under the effect of a cycloplegic.

Complaints of headaches combined with drowsiness are not uncommon. These symptoms will not disappear by wearing correcting glasses when they are found necessary, but will nearly always pass away by administering successful treatment to the affected conjunctiva additionally. Among the less frequent affections resulting in unpolished and uneven surfaces of the conjunctiva, are deeply seated calcareous deposits, overfilled meibomian ducts, chalazia, post results of trachoma, end processes of operations upon the lids, enlarged pinguecula, low grade scleritis and episcleritis, pterygia and neoplasms. Following the reduction of the above affections that had been accompanied by drowsiness, it was noted that this symptom usually disappeared. Drowsiness is a constant complaint when fully developed pterygia are present, but at this time we see very few of such cases in this locality.

Drowsiness is a frequent complaint when vision is markedly reduced in both eyes and unattended by pain in the eyes. The usual painless ocular affections that reduce vision in both eyes are: cataracts, optic atrophy, low grade optic neuritis, retinitis and choroiditis, degenerations in the fundi, and dyscrasias in the media.

Many who have had lenticular opacity, sufficient to reduce vision considerably in both eyes, suffer from excessive drowsiness and I have observed this symptom disappear following a successful extraction of a cataractous lens when good vision was obtained after the operation. Those who employ the eyes for continuous close work, apply most frequently for relief of drowsiness as they find it embarrassing and at times impossible to keep awake during working hours, although they are in good health, live regular lives and have plenty of natural sleep at night.

SUMMARY

Drowsiness is registered as a most annoying symptom at times and as such deserves a close search for its possible source. After the elimination of possible constitutional disturbances that might produce it at the time of consultation and previous medical conditions of which it may be a sequel, a study of possible ocular factors that create drowsiness, deserves our close attention. The usual ocular factors responsible for drowsiness in my experience are: a, roughened and uneven surfaces of the conjunctiva from whatever cause unattended by pain in the eyes; b, marked reduction of vision in both eyes unattended by pain in the eyes.

Congenital Dislocation of the Hip

ETHAN H. SMITH, M.D.,
San Francisco, Cal.

ETIOLOGY

Nothing better on the etiology of congenital dislocation of the hip has been offered than the speculative discourse in Gross's *System of Surgery*, page 38, volume 11. This chapter is well worth reading, although it gives exactly what we know today, which is nothing definite.

DIAGNOSIS

Before starting in with the actual diagnosis of congenital dislocation of the hip, I wish to urge all members of the profession to use their influence to impress on the younger men in the profession that they must inspect most carefully every infant that comes into their hands, stripped naked, and scrutinize carefully each and every part of the child's body and limbs. It is only by this means that they can acquire skill in readily detecting abnormalities. By detecting deformities as early as possible, the general profession can increase the efficiency of the surgeon in his attempts at restoration.

It is not difficult to make a fairly accurate diagnosis of a congenital dislocation of the hip without a radiogram. To be sure, the clinical diagnosis should be verified by proper radiographic investigation. By placing the naked infant on its back on a table, and then comparing the length of the lower extremities in the extended position, it is easy to see whether or not there is any shortening. Grasp the pelvis in one hand so as to hold it firmly on the table, while with the other hand, grasp the femur just above the knee, and then see whether or not the head of the femur can be pushed upward on the dorsum of the ilium, and dragged downward again to its normal position. If there is a dislocation, the head of the bone can be pushed upward and back for from one to two inches; while on the normal side it will be found that the head of the bone is anchored to the acetabulum, so as to prevent abnormal mobility. By placing the tips of the fingers over the medgluteus medius region, and then rotating the femur with the other hand, the head of the femur can be palpated underneath the gluteal muscles, moving in abnormal fashion when dislocation is present.

In studying a radiogram of unilateral dislocation, one of the first things to be observed is the great discrepancy between the innominate bones of the two sides. On the dislocated side, the innominate bone in its lower two thirds will be greatly lacking in development. The earlier the dislocation occurs, the greater will be the lack of development. The femur will be found smaller in diameter, the great trochanter, perhaps, not fully developed as it should be at that age. The epiphysis of the head of the bone will be almost invisible because of lack of mineral salts, and much smaller than that on the normal side. The head of the dislocated femur will be found to be from one to two inches upward and backward from its proper location.

It has been known, since this condition was first recognized, that it occurs much more frequently in girls than in boys. In the time of S. D. Gross, there were about six and a half times as many girls afflicted as boys. Other authorities give the ratio as nine girls to one boy. In my own experience, I have

seen eleven girls to one boy with dislocation of the hip. When it occurs in children old enough to walk, they will be observed to incline the pelvis forward on the thighs, compelling them to throw their shoulders back, producing marked lordosis in the lumbar spine, and to walk with a peculiar waddling gait. In extreme cases of bilateral dislocation, the child cannot walk without resting one knee against the other and waddling along like a duck.

In the adult, who has never been treated, it is easy to see the upper extremity of the femur punching up loosely under the gluteal muscles every time weight is born on the corresponding limb.

PROGNOSIS

In unilateral cases, properly reduced at the proper age, ninety per cent. of all patients should recover with perfect function, and fifty per cent. ought to recover with well nigh perfect anatomical restoration of the joint. In bilateral cases, much depends on the temper of the patient and the cooperation of the parents. If a child will learn to walk while in the plaster of Paris dressing, and persistently get about, quite as good results are possible as in the unilateral cases.

Most children have not the pertinacity to stick to walking, and sit down and do nothing. In such cases, the results are variable. However, it is possible to get an anchorage of the head of the bone to the pelvis, and give to these children some sort of hip joints. They may limp somewhat, but they will be comfortable throughout the rest of their lives.

Many more men ought to know how to take care of congenital dislocation of the hip than are now engaged in the work. On the other hand, there are about ten times too many men meddling with congenital dislocation of the hip without ever having had any sort of adequate training.

One hip out of five hundred requires an open operation. By cutting into the hip, the surgeon still further weakens the already half developed tissues. It is unnecessary and indicates lack of understanding, or lack of training in this work, or both.

There is no semblance whatsoever between this condition, and traumatic dislocation of the hip. The individual who says he reduces these hips, and then lets them go, certainly has never given careful scrutiny to a radiogram of a congenital dislocation of the hip, or he would see why such treatment is worse than folly.

My conclusions are based on twenty years' experience, in addition to which I had the privilege of working with the late Professor Albert Hoffa, of Berlin, for five months. During that time, he averaged seven cases a week. He also showed us many cases which he had returned to him every four weeks —such cases covering a period of two years. Every third month he had a radiograph of each of these cases. My prognosis is based, not only on my own experience, but on the results obtained by Hoffa, in his clinic at the University of Berlin.

TREATMENT

I shall not refer to what others have said or written, about at what age treatment should begin. Experience with a large number of cases has taught me that eighteen months from birth is the best time to reduce these hips.

By effecting reduction at this age, we avoid distortion of the head and neck of the femur by pressure against the more or less flat surface of the dorsum of the ilium underneath the strong gluteal muscles. We prevent stretching and changing of the capsular ligament, and also other changes about the acetabulum. Also we prevent much of the shortening and structural changes in the adductor group of muscles, which, as time goes on, adds greatly to the difficulty of reduction.

In some of these patients at eighteen months, it is possible to place the head of the femur in the acetabulum, without anesthetic and without pain. However, it is not possible to relax the muscles and put the hip in exact position without an anesthetic. These hips, at this age, can be so easily reduced, that there is very slight traumatism. There is little or no risk from manipulation, and within a few days, the child can be up and walk about with a plaster of Paris dressing.

The adductor muscles should be so relaxed that the outer side of the knee will lie on a plane with the sacrum when the child is lying on its back on a table. The femur must be placed at a right angle to the long axis of the spine.

When the head is in the acetabulum, it can be readily palpated just above the adductor tendons, while the femur is rotated by the opposite hand. The application of the plaster of Paris is of the utmost importance. The grossly careless and sloppy method in applying plaster over an indifferently applied lot of sheet wadding is a parody on plaster of paris work in these cases.

A piece of stockinette shirting, long enough to make a union suit for the child, should be had. A trouser leg is cut from this for the extremity involved. The upper part of this is fastened at the top by straps of gauze pinned over the shoulder like suspenders. The trouser part is smoothly tacked in place around the thigh, and to a point below the knee. Next, a sheet of three eighth inch white wool felting is cut and shaped so as to make a clout for the child's trunk and a trouser leg for the thigh to the knee. This is cut and shaped so as to stitch smoothly around the child's hips and thigh like a well fitting breech clout. A pad, about three by four inches, with the corners rounded, and the centre cut out like a doughnut is placed over each anterior superior spine of the ilium to prevent pressure sores. The surgeon will now feel to see that the head of the bone is still in the acetabulum, and adjust the child's body on a pelvic rest with the shoulders elevated, and assistants holding the legs and body in proper position. He then proceeds to put on the plaster. The plaster should extend up to the level of the ninth rib. It should also extend to the knee, but not below it. Across the groin a piece of yucca-stem wood should be incorporated in the plaster to reinforce it. After having trimmed the plaster of Paris dressing so as to provide ample clearance about the perineum and back of the knee, the stockinette shirting should be reversed on the outside of the plaster dressing and stitched firmly so as to make an outer covering. It has been urged that these little folks soil the dressing and stain it with urine so as to destroy the dressing in a short time. This can be obviated by covering the dressing with stork

sheeting stitched in place so as to cover the plaster of paris at exposed parts. This dressing should remain in place for three months, during which time the child should be urged to walk.

A raised shoe two inches in height should be placed under the foot on the affected side. Experience has taught that two inches is about the proper height for the best results.

At the end of three months, the dressing should be renewed with the hip in the same position. At the end of six months, the hip should be tested with the dressing removed to see whether or not it is safe to bring it into the modified position.

If, on cautiously bringing the femur down from a position at right angles to the long axis of the spine, we encounter some resistance to adduction, we may know that the hip is ready to be brought into the semiextended position. We may feel encouraged that we are going to have a good result also. The hip, under such circumstances, is placed in plaster at an oblique angle to the long axis of the spine, and left for three months. At the end of that time, it may be well enough to permit the child to walk with a plaster of Paris girdle, or, it may require three months longer in the semifiexed position.

This is a matter that requires both judgment and experience to learn to do readily. We may judge somewhat by the radiograph made for diagnostic purposes. If there has been an unusual deviation from the normal due to arrested development, we must keep the limb in restraint a much longer time than would otherwise be necessary.

The plaster of Paris girdle is my own contribution to the treatment of this condition. It is merely a corset, not as long as would be required for injuries to the spine, and coming well down over the great trochanter on each side. It is applied over a three eighth inch wool felting so as to prevent pressure sores on the trochanter, and other bony parts. With this, I let a child run freely. It prevents redislocation. I keep this girdle on for from six to twelve months after removing the restraining plaster of Paris spica.

I have a radiogram of a patient of mine, now twenty years of age, whose hips I reduced before she was two and one half years of age, which shows normal restoration of the hip joints. This young lady had both hips dislocated, and had the most exaggerated deformity, as a result, of any child I have ever seen. Now she has two very perfect hip joints. She was a very successful basket ball player during her high school course.

There is no magic, no abnormal skill required in this work. However, it must be learned exactly as a mechanic would learn any other part of a trade. After having learned the mechanical technic, he must adhere to that absolutely in detail, and then there is no reason why his results should not be good in nearly all cases.

528 Flood Building.

An Effective Method for the Treatment of Acute Middle Ear Infections and the Prevention of Mastoiditis

ADOLPH I. SCHWARTZ, M.D.
New York.

It is a truism to say that every case of middle ear infection is a potential mastoiditis. As is well known numerous cases of otitis media are accompanied by early signs of mastoid involvement, as evidenced by tenderness of the mastoid process and later by sagging of the posterosuperior portion of the drum. These are the socalled cases of threatened mastoiditis. If to these be added continuous pain accompanied by insomnia, and a positive culture from the ear, the diagnosis becomes a certainty. In the minds of many surgeons the indications for operation are then imperative, but it frequently happens that despite the definite clinical picture, operation reveals no involvement of the mastoid cells and only infection of the mastoid antrum. The surgeon then justifies his precipitate operation on the score of prevention and on the further claim that the antrum is best drained from behind.

It is conceded that the most important question of midde ear infection is one of drainage. During the past several years the writer has tried by various means to facilitate this drainage and thus prevent the stagnation of pus with consequent infection of the mastoid cells. It is well known that mere incision of the drum is not always sufficient to establish thorough drainage. This is explained by the anatomical configuration of the middle ear. The floor of the middle ear is two or three millimetres lower than the lowest part of the drum membrane, so that even the most extensive incision will not reach to the dependent portion of the tympanum. There is a similar dipping of the floor of the antrum below the aditus. It is obvious therefore that no thorough drainage is possible by means of incision alone, nor is irrigation of the external auditory canal capable of doing more than the mere washing out of the pus. The Hays suction tube is simply a substitute for irrigation but does not materially aid drainage, although its aim is to do away with pressure from without. Mastoidectomy on the other hand is an operative attempt to remove pressure from within, for the purpose of preventing extension of infection. To facilitate drainage from the dependent portion of the tympanum and reduce pressure from the vault to the antrum the writer has devised a vacuum suction method as a substitute for the removal of pressure by operation.

The principle of this method consists in the creation of a vacuum in the external ear canal, which in turn draws out the pus from the tympanum and reduces the pressure within the middle ear. For this purpose a special tube was devised (Fig. 1). The tube is used in connection with a Yankauer suction

apparatus. The end marked A is inserted in the ear, firmly enough to make the external canal air tight. The finger is placed on end C to create a vacuum while suction is exerted by the Yankauer apparatus at B. As soon as enough vacuum is produced the patient will begin to wince with pain and the finger is removed from C. The operation is repeated several times. Inspection of the ear then shows that the canal is full of pus, obviously this pus must have come from the tympanum.

In addition to the induction of a vacuum and the removal of the pus thereby, further drainage can be obtained by changing the position of the head. As stated above, the tympanum with the head in the vertical position is lower than the lowest portion of the drum. If the patient is in a horizontal position and the head tilted the floor of the tympanum and the antrum are tipped and the pus contents are drained by gravity. It is therefore obvious that it is necessary to have the patient both during treatment and in the intervals with the head in a horizontal position. It is evident that the two factors in the matter of drainage and removal of pressure are the vacuum and gravity principles. The creation of the vacuum also induces a transitory hyperemia, which is probably beneficial.

For the actual procedure a long incision is made from the lowest portion of the drum to the superior wall of the canal. In withdrawing the knife the incision is extended one quarter of an inch along the superior wall. Where there is marked mastoid tenderness, a short posterosuperior cut is made so that a Y shaped incision with a V shaped flap results. This ensures better drainage from the antrum. After the two incisions are made, we proceed as above with the induction of a vacuum. As after treatment the following prescriptions are given:

I.		II.
Sodium Chloride	0.30	Sol. Argyrol 10-20% 16 c.c.
Sodium Citrate } Resorcin }	aa 1.20	To be used as nose drops
Aqua dist.	30.00	
To be used as ear drops.		

Prescription No. 1 is dropped into ear canal to produce osmosis, and the argyrol in both nostrils to disinfect the nares and the eustachian tube. For the creation of a vacuum an apparatus (Fig. 2) is improvised for the patient to use at home. The air from the bulb is expressed, the tip of the glass nozzle is inserted into the ear canal and allowing the bulb to expand a vacuum is produced. An ice bag to the back of the ear is also given when mastoid tenderness is elicited. The icebag is applied constantly for twenty-four to forty-eight hours or until tenderness subsides.

Thus far I have treated several hundred cases of middle ear infection with most satisfactory results. In this group there have been numerous cases which were definitely diagnosed as acute operative mastoiditis and others which were declared by competent otologists to be in urgent need of operation.

While I am not willing to make wildly enthusiastic assertions about the method of treatment, I can assert that since I have employed it I have prevented mastoiditis and saved from mastoidectomy patients who were about to submit to operation.

To illustrate the effectiveness of this method the following cases are reported:

Case I.—L. J., fifteen years old, was seen on March 17, 1922. He complained of severe pain in the left ear for five days and inability to sleep. Mastoid tenderness and bulging of the drum were present. Paracentesis was performed under gas-oxygen anesthesia. Good drainage was established but the symptoms were not relieved. March 19th, a Y incision was made and better drainage obtained. March 20th, no marked improvement. A radiograph showed haziness of the antrum and septa throughout the mastoid process. There was no evidence of absorption. March 22nd, the patient not feeling better consulted a Brooklyn otologist who advised a mastoid operation. March 23rd, a second x ray picture showed progressive pathology manifested by an increase in the haziness. March 24th, patient consulted a New York ear surgeon who after raying the patient for the third time strongly advised mastoidectomy. The appearance of the drum, at this time, showed less sagging and the deafness was decreased. Upon the finding of these changes the patient was advised to continue under the vacuum suction treatment. March 25th, patient had a comfortable night. Pain, headache and tenderness decreased and thereafter continued to improve until completely free of symptoms. April 16th the patient was discharged as cured.

Fig. 1.—Improvised vacuum apparatus devised by author.

Case II.—R. S. was seen on March 3, 1923. Following an attack of influenza she was suffering from pain in the right ear for two days. She also complained of headache and inability to sleep. Examination revealed considerable tenderness of the right mastoid and bulging of the drum. Myringotomy was performed and the vacuum suction treatment was instituted. An ice bag was applied to the back of the ear. March 4th, right ear was draining freely. Mastoid tenderness persisted. Icebag continued. March 5th, patient spent a restless night and complained of headache. Sagging of the drum noticed. The Y shaped incision made. Radiographs showed moderate haziness of the cellular septa and a decrease in the illumination of the antrum. A smear showed a moderate number of pneumococci. March 6th, the patient feeling bad consulted an ear surgeon of repute. She was advised to go to the hospital for a probable mastoidectomy, but refused to do so. March 7th, another paracentesis was made and the vacuum suction applied. This was followed by an improvement in the condition of the patient. For a few days she felt better and the tenderness was markedly reduced. March 14th, headache, insomnia, and bone tenderness returned. A fourth paracentesis was done. This was followed by better drainage. The patient felt better for two days. March 16th, the headache and the pain in the ear very severe. Bone tenderness increased. A second radiograph showed an increase in the haziness and a beginning absorption of the septa. Vacuum suction was continued and on April 10th the patient was discharged as cured.

Practical Therapeutics

NONSPECIFIC THERAPY IN ERYSIPELAS

EDWARD H. AHLSWEDE, M.D.
Buffalo, N. Y.

In the treatment of erysipelas of the face stress must be laid on the stimulation of the defensive forces of the system to a maximum, in order to counteract as far as possible the effect of the streptococcic toxines. The fact that a toxin formation occurs in streptococcic infections has been proved beyond doubt, though the quantities are so small and their peculiarities so problematic that we have not yet succeeded in using them for passive immunization purposes. On the other hand, investigations, chiefly of Kolle and Schottmueller, have proved that the injections of a streptococcic serum frequently exert a powerful influence on furunculosis, erysipelas and other streptococcic disturbances. Long before the era of nonspecific parenteral protein body therapy, Kolle already drew attention to the fact that the serum of the human body as such possessed antistreptococcic qualities.

Since recent advances made in our knowledge of nonspecific therapy, we can understand why the results obtained with injections of streptococcic serum in the corresponding diseases varied so much and why in particular it was not possible to prepare a homogeneous serum which guaranteed more or less the same reliable effect in each case. These streptococcic serum injections we know now were strictly nothing but a different form of parenteral protein body therapy or of the nonspecific stimulation therapy in general. Recent investigation, particularly with protein bodies, has shown, furthermore, that physical processes more than chemical alterations account for the change in the condition of the blood plasm which in its turn exerts the impeding effect on the development of the streptococci. This explains also why a prolonged immunity could not be obtained in this disease, as the change in the physical condition of the blood quickly turned back to the normal.

During the past few years the control of the sinking velocity of the red blood corpuscles has furnished a practical means for judging both the biological condition, the reactivity of the infected system, and the effect of the applied therapeutic measures. We know that a pronounced increase of the sinking velocity of the red cells occurs chiefly in acute inflammatory processes with rise in temperature, also in processes in which a sudden resorption of large masses of cell protoplasm takes place, and furthermore in chronic inflammatory alterations, which apart from subjective disturbances need not cause any visible tissue alterations and yet may conceal an extensive inflammatory process without necessarily causing rise in body temperature. With the streptococcic disorders in question, and in particular with erysipelas of the face, the sinking velocity of the red blood cells is an exact measure for judging the defensive reaction of the system. It is a poor sign if no increase in the sinking velocity of the red cells takes place in a case of erysipelas in which the general constitution is involved. These are in fact the cases which demand immediate stimulation therapy.

On the other hand, the reaction also furnishes a good measure for judging whether it is advisable to increase the strength of the stimulation in a given case or whether the reduction of the sinking velocity of the corpuscles makes an interruption of the stimulation necessary. It is probable that these alterations in the sinking velocity of the red cells are due to an alteration in the electric charge of the corpuscles (Fahraus). Upon the addition of a precipitating electrolyte, e. g., after the injection of a strong protein stimulant, the magnetic forces outweigh the discharging forces, with the result that a conglomeration and sedimentation of the blood corpuscles take place.

Of the nonspecific stimulants which have a decided influence on the sinking velocity of the red cells the protein preparations have proved the most effective. Schmidt used ordinary milk for the purpose originally, which, however, did not always prove reliable, for which reason milk albumen solutions were prepared, and actually furnished better results. Now it has been shown (Zimmer) that there is a distinct difference in the effect of nonspecific protein preparations depending on whether they have been heated before injection or not. Thus, if a casein solution is heated a short time only it may retain its full efficacy; if the same preparation is heated for several hours it will be found to have lost its effect.

In accordance with our conception of the purely physical alteration of the condition of the blood plasm, diluted solutions of casein will not be borne as easily as concentrated solutions. The five per cent. solution of casein has in fact proved the best and most effective for all purposes. As the treatment of erysipelas requires quick and energetic stimulation of the protoplasm of the bodycells those nonspecific stimulants will be preferred which have a quick action. Furthermore, the intravenous mode of injection will also be preferred, as experience has shown that the stronger effect of a nonspecific stimulant is attained by way of the veins than by intramuscular injection (buttocks). To avoid overstimulation, that is, a possible "proteinogenous tiring," in extreme cases a "proteinogenous cachexia" of the system, the control of the sinking velocity of the red cells and the blood picture will make it possible to determine the stage when further stimulation is contraindicated. While no hard and fast rules can be laid down, it may be said in general that the older the process and the less acute, the smaller the stimulating dose should be. An acute case of erysipelas, therefore, would demand heavy stimulating doses.

RESULTS

The results obtained in the treatment of two hundred cases of erysipelas of the face led us to support the nonspecific therapy by specific measures. Thus, intravenous injections of salicylic acid preparations and iodine compounds have proved effec-

tive, the latter probably partly on account of their nonspecific constituent.

We have seen less benefit from specific antistreptococcic serum as the antitoxin content depends too much on the particular animal employed in the preparation and also seems to fluctuate with the particular strain of streptococci used. The effective support, however, obtained from the application of red light rays to the erysipelatous skin surface must be mentioned here. The antiphlogistic influence (2) of the long wave rays in many cases helps to shorten the duration of the disease and particularly helps to allay the sensation of tension and irritation of the skin.

SUMMARY

Energetic nonspecific stimulation supported by red light treatment are particularly indicated in erysipelas treatment. Specific sera promise little, as the antitoxin content fluctuates with the particular strain of streptococci and the animal used in the preparation.

THE SURGICAL TREATMENT OF OZENA

John A. Glassburg, M.D.

New York,

Assistant Visiting Otologist and Rhinolaryngologist to the New York City Children's Hospital; Assistant Rhinolaryngologist to St. Joseph's Hospital; Surgeon to the Ear, Nose, and Throat Department of the Stuyvesant Polyclinic.

Of all distressing nasal diseases, ozena ranks first in antiquity, intractability and obnoxiousness. The antiquity is demonstrated by Jonathan Wright (1) who found the following passage in the Kathubot treatise of the Talmud; "Samuel says that the polyp shows itself by a bad smell of the nose," and the Talmud was compiled during the first four centuries of the Christian era. The intractability of this condition was shown by Celsus in his *De Medicina* (2) where he says; "It should be recognised that it is hardly possible to cure this disease," and Celsus lived in the second century. The obnoxiousness of ozena is vouched for by the patient and his family, his friends and all who come in contact with him, for not only is the fetor a source of personal affliction, but a cause of making the sufferer loathsome to all about him. Polypi, septal deviations, hypertrophied turbinates, exostoses and sinus disease *per se* may cause nasal obstruction and painful subjective symptoms, but ozena will cause all these, and in addition, because of the disgusting fetid odor, exiles the sufferer to social isolation.

Unfortunately the progress in the treatment of this affliction since the time of Celsus has not been very marked, and, generally speaking, his gloomy prognosis is as true today as it was then. However, there is a certain type of case in which operative intervention will cause a marked alleviation of the symptoms and often a complete cure; and because of the success of the treatment in these cases, this paper is presented.

The success of the treatment depends upon the proper selection of the case which, in turn, depends upon the etiology, and this is often very difficult to determine. It must be understood that ozena is really a symptom and not a special disease. It is the end process of an atrophic rhinitis, but inasmuch as ozena is often not present in atrophic rhinitis, the cases presenting this particular symptom may be considered separately, at the same time fully recognizing the association of ozena and atrophic rhinitis. The etiology is conveniently classified in the following:

ETIOLOGICAL CLASSIFICATION OF OZENA.

I. General.—a. Malnutrition. b. Constitutional diseases. c. Physiological atrophy of old age.

II. Local.—a. Congenital malformations. b. postoperative atrophy. c. Mechanical obstruction. d. Infections and sinus diseases.

III. Neurotrophic.

Malnutrition is commonly observed in patients suffering from ozena. Poverty and unsanitary conditions are common associates. Ozena is a disease most often seen in clinics and but infrequently in private practice. According to Goodale (3) it is most common between the ages of five and nineteen, and is twice as frequent in females as in males. Lack (4) found in 150 cases that nearly three fourths of the patients were females and just over one fourth were males. Gerber (5) gives the proportion as 293 females to 117 males. Wyatt Wingrave's (6) figures as to the age at which the disease sets in are interesting. In a series of sixty cases he found that six commenced under nine years of age, twenty-eight between nine and fifteen, nineteen between fifteen and thirty, and seven over thirty. Ozena is a disease of youth. Chlorosis is often associated with it. Perhaps this is the reason for the increased incidence in females, chlorosis being such a common disease in girls of that age. Syphilis and tuberculosis have been described as causes, but the majority of modern observers Moure (7) and others state that most of the cases of ozena occur in otherwise healthy individuals. The physiological atrophy is concomitant with old age and is a part of the general atrophy throughout the body.

Among the most common congenital malformations are defective development of the inferior turbinates, shown by Zaufal (8), abnormal width of the nasal fossæ, reported by Meisser (9), extreme shallowness of the nares, demonstrated by Sauvages (10), short septum, or short nasal fossæ, noted by Hopmann (11), and depression of the nasal arch, with wide fossæ, described by Gerber (12). Atrophy following nasal operations involving extensive destruction, especially of the inferior turbinates, is not an uncommon etiology. The mechanical obstruction is caused by adenoids, as shown by Grunwald (13), septal deviations, or hypertrophied middle turbinates. Berliner (14) believes that the enlarged middle turbinates press against the septum, cause a stagnation of the nasal secretion, with a consequent atrophy of the mucous membrane, and that the fetor is due to the contact of the air with the stagnant secretion.

Among the infections, purulent rhinitis is of great

importance. Moldenhauer and Bosworth (15) believe that all cases of ozena originate in the purulent rhinitis of childhood. Shurly (16) states that he has never seen a case of ozena which originated after twenty years of age that was not syphilitic, and the syphilitic type of ozena is now recognized as a distinct entity, and as a rule, is not included under the head of the ordinary atrophic rhinitis, which is now being considered. Sinus disease as a cause of ozena has come to the fore in recent years. The recognition of sinusitis as an etiological factor is concomitant with the progress made in the study of the accessory nasal sinuses. To Carl Michel (17) belongs the credit of having first impressed the profession with the importance of the accessory sinuses as a cause of ozena. This was further emphasized by Tissier (18) who laid stress on the diseased ethmoid cells, although the frontal and maxillary sinuses were found to be also involved. In a series of twenty-five cases of ozena, Grunwald (19) found suppuration of ethmoid cells alone in six, in the ethmoid cells and other sinuses in four, in the sphenoidal sinus in three, in the antrum in one, in the frontal sinus in one, and in multiple sinuses in three. Bronner (20) found suppuration of the maxillary sinuses in about one quarter of his cases. This type of ozena due to sinus infection holds out the greatest prospect of cure.

The neuropathic theory of causation can be dismissed with a few words, being based on the fact that improper innervation from the trifacial nerve causes a nutritional disturbance in the nose. Zuckerkandl, however, believes that the causation is inflammatory and the procedure is first an hypertrophy and then an atrophy, and that the fetor is due to the degeneration of the columnar epithelium, a process similar to that which occurs in catarrhal inflammation of the lining of the uterus.

From a therapeutic viewpoint ozena may be considered under two categories, surgical and nonsurgical. The surgical types are those due to mechanical obstructions, diseases of the accessory nasal sinuses, and some of the varieties of the congenital malformations. The nonsurgical types are those due to malnutrition, constitutional diseases, the physiological atrophy of old age, and postoperative atrophy. Some of the postoperative atrophies do at times respond to surgery of the inferior turbinates, as shown by the paraffin injections and resection and fracture of these structures. The type of ozena that gives the most satisfactory results after operation is that due to diseases of the sinuses, or to a mechanical obstruction caused by a deviated septum, or hypertrophied middle turbinates. To illustrate the effect of treatment in these conditions, the following cases are presented:

Case I.—Anna R., eighteen years old, had had a bad smell from the nose ever since she could remember. She had used various washes, oils, and vaccines with no beneficial results. Her physical condition was good, with the exception of carious molars and a moderate degree of pyorrhea. The Wassermann reaction was negative and the blood count showed no anemia and particularly no chlorosis. Examination of the nose showed polypoid degeneration of the middle turbinates on both sides, hypertrophy of the inferior turbinates, thick, foul smelling greenish crusts over various parts of the mucous membrane and a thin white streak of pus over the anterior end of the middle turbinates. This streak reappeared after being wiped off. There was no pain or tenderness over any sinus.

The polypoid anterior ends of the middle turbinates were removed, and there followed a visible discharge of pus. The ethmoid cells were exenterated. The patient was then given an alkaline nasal douche consisting of carbolic acid twenty drops, sodium biborate and sodium chloride each equal parts to make three ounces. Half a teaspoonful of this powder was dissolved in hot water and the nose was syringed three times a day. Care was taken to keep the head down so that the water did not trickle back through the eustachian canals into the ears. A soft all rubber ear syringe was used. It is preferable because the soft rubber bends and can do no injury to the parts it comes in contact with.

At the end of one month the nasal irrigations were discontinued. The fetor was gone, and there was some improvement in the sense of smell which had been entirely lost. In addition, there was improved nasal respiration.

Case II.—Samuel L., sixty-five years old, complained of headache, loss of the sense of smell and bad odor from the nose. The fetor had existed since childhood, the headache was of about ten years' duration and the anosmia of about five years' standing. The patient's physical condition was good, except that he had a cataract on one eye. The Wassermann reaction was negative and the blood count was normal. Examination of the nose showed an almost complete obstruction due to polypi. The middle turbinates could not be seen, due to the obstructing polypi. Thick, foul smelling greenish crusts covered the mucous membrane. Röntgenography showed shadows over both ethmoid sinuses. The polypi were removed, the anterior ends of the middle turbinates were cut off, and the ethmoid cells were exenterated. Upon curretting the ethmoid cells there issued a free discharge of foul smelling pus. The patient was then placed upon the alkaline wash previously described. At the end of three weeks there was no vestige of an odor, the headaches had ceased and the sense of smell was returning. The patient feeling relieved ceased coming and further trace of the case was lost.

Case III.—Helen P., twenty-four years old, has been wandering from physician to physician and from clinic to clinic for the past six years seeking relief from a very distressing fetor. She had used nasal douches, oils, vaccines, electricity, and topical applications with no improvement. Her physical condition was good. The Wassermann was negative and the blood count was normal. Examination of the nose showed the characteristic thick, foul smelling, greenish crusts and a thin white streak of pus over the anterior end of the middle turbinate on the right side. The left nostril revealed a normal rhinoscopic picture. The septum was moderately deviated and the turbinates on the right side appeared normal. Röntgenography showed shadows over the right

frontal and right ethmoid sinuses. The ethmoid sinus on the affected side was opened up and the cells curetted. Free drainage from the frontal sinus was established. The patient was then put on the alkaline wash and at the end of one month the fetor was entirely gone.

Case IV.—Mandel S., nineteen years old, student, had had a fetor nasi for at least three years that he was aware of. Previous to that time, ever since he had been a child, he had been subject to attacks of acute rhinitis. His physical condition was below par. He was under weight, rather poorly nourished, sallow complexioned and his blood count showed a secondary anemia. The Wassermann reaction was negative. Examination of the nose showed a thin white streak of pus coursing along the anterior end of the right middle turbinate. The mucous membrane of the septum and of the lateral sides of the nasal cavities was covered in various places by the thick, greenish foul smelling crusts. Otherwise the rhinoscopic picture was normal. Röntgenography showed a definite shadow over the right ethmoid sinus. The ethmoid sinus was opened up and the cells exenterated. As this was being done there was no visible discharge of pus but there was a marked increase in the stench. The alkaline wash was used for two weeks and at the end of four weeks no odor at all could be detected.

SUMMARY.

I wish to reiterate that in ozena we have a most difficult and baffling disease to cure, but there is one form of it, namely, that due to sinus disease which is amenable to treatment. Medical means, washes, oils, vaccines and topical applications are practically useless, so far as a permanent cure is concerned. The only form of treatment in this condition is surgical and based on the well established and time honored principle that "wherever there is pus evacuate."

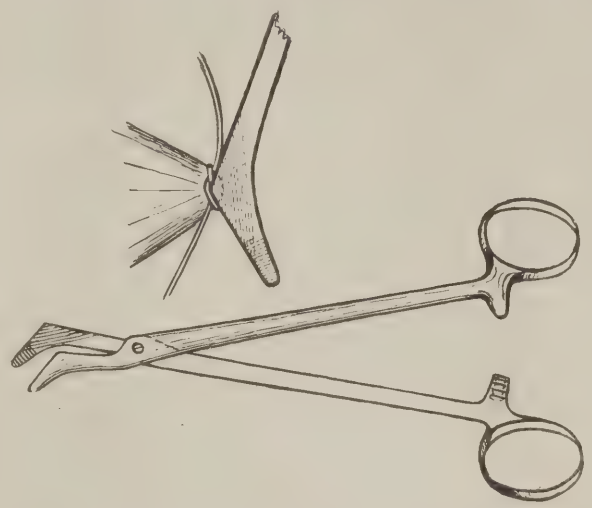
ARTERY FORCEPS FOR TYING OFF BLEEDERS IN DEEP, NARROW CAVITIES.

Alfred Kahn, M.D.
New York.

Bleeding vessels in deep narrow cavities are usually tied off by first grasping them in the artery clamps. Ligatures are then slipped down over each clamp, passed over its tip, looped around the vessel and tied. The whole procedure is quite easy, except the passing of the ligature over the tip of the clamp. The nose of the instrument is embedded in the tissues and it is often troublesome to raise it sufficiently out of the bed of tissue to pass the ligature over and around so that it can be tied in place. The instrument devised is presented herewith, showing the clamp partially open. The artery is grasped by the forceps from the point a, instead of at the nose of the instrument. It is then quite easy to slip the ligature down and over the apex of the clamp, when the vessel is promptly tied.



48 East Forty-Ninth Street.

Poikilocytes in Otherwise Normal Blood.—John G. Huck and Rena M. Bigalow (*Bulletin of the Johns Hopkins Hospital,* November, 1923) report the case of a patient who was observed for two years, fresh preparations of whose blood showed that between fifty-three and eighty-four per cent. of the erythrocytes had an elliptical or elongated form; hanging drop preparation showed from fifty-nine to seventy per cent., and stained smear from twelve to forty per cent. The blood of nine members of the patient's family was examined, and only that of the patient's mother showed anything unusual. Her blood presented the same anomaly, from fifty to eighty per cent. of the erythrocytes in fresh preparation were of an elliptical or elongated form. The patient had been used several times as a donor, without untoward effects on the recipients. Only five cases of this condition have been observed, occurring in the white as well as black races. From the authors' studies of this case they conclude that this particular or special poikilocytosis is an inherent property of the red blood cells or an anomaly of the bone marrow, and that the patient's serum is without effect on normal erythrocytes.

Historical Medicine

Notes on Acute Rheumatism by Dr. Thomas Watson, 1824-1843*

G. ARBOUR STEPHENS, M.D.,
Swansea, Wales,
Consulting Cardiologist King Edward VII, Welsh National Memoriam Association

The American edition of Dr. Thomas Watson's *Lectures on The Principles and Practice of Physic* first appeared in 1845 under the editorship of D. Francis Condie, M. D., secretary of the College of Physicians. It was published by Lea and Blanchard of Philadelphia. In the preface by the editor we read: "If by the few notes he has been induced to append to the present edition, the Editor has succeeded in adding in some slight degree to their value he will be amply repaid for his labour."

One of these notes is as follows: "Without pretending to advocate the employment of blood letting in every case of cyanotic tonsillaris and of acute rheumatism, we must dissent from the correctness of Dr. Watson's position that even though the fever be high and the pulse hard, it may not be worth while to bleed for the sake of subduing inflammation which in these affections is attended with so little danger. When acute rheumatism occurs in young, robust, and phlethoric habits and is attended with considerable fever, and a hard and accelerated pulse, we know of no remedy from which such decided advantage is to be obtained as from a well timed resort to the lancet." This note of Condie's follows this sentence of Watson: "The subsequent debilitating effect of the loss of blood upon the system may be more certain and more hurtful than the effect of the bleeding upon the local inflammation is likely to be beneficial."

These statements were made at the time when knowledge of diseases of the heart was in its infancy. For Dr. Watson tells us: "I can remember indeed the time when disease of the heart was thought to be a very rare thing; but it is now well known to be one of the commonest of disorders, and it connects itself with a variety of other affections with which it was formerly supposed to have no connection."

Watson's knowledge, even in those early days of heart work, was wonderfully sound for he states in his book: "That the chance of the joint affection being complicated with rheumatic conditions is the greater in proportion as the patient is the younger." Another dictum of his that strikes us with modern freshness is to the effect that the inflammation of the lining membrane does not always compromise the life of the patient for: "They are fatal at length in ninety-nine cases out of a hundred through the alterations to which they lead in the muscle wherewith they are connected." One reason, he tells us, why the disease of the heart used formerly to be overlooked was that its natural dimensions were not attended to because "it is not easy to form any very precise estimate of the size of a healthy heart."

In later times Goodhart has emphasized the difficulty of estimating hypertrophy or dilatation and we all know how difficult it is to differentiate between dilatation and pericarditis, although x rays have been a very great assistance. Even with x rays we want a definite point in relation to the trunk to which we can correlate the heart and the one that commends itself to me is the point half way between the right abdominal process and the left anterior superior iliac spine.

Watson tells us with regard to the sounds of the heart that there had been much recent discussion as to the physical causes of these sounds. He confesses his inability to measure satisfactorily the duration of the two sounds, but as to their causes he is very dogmatic. He tells us that the second or diastolic sound used to be ascribed to the contraction of the auricles, but that was quite a mistake. In a recent number of the *Lancet,* however, Dr. Pinchin and Gloyne state: "At the apex of the heart the auricular beat . . . could be heard as a loud regular beat (sic)." "In truth," says Watson, "the auricular contractions are very feeble, and not attended with any appreciable noise." "I have," he adds, "no doubt, that the second sound is produced mainly, if not altogether, by the sudden shutting off of the flood gates placed at the mouths of the two great outlets of the heart."

As to the first sound, he is of the opinion that the abrupt closure of the mitral valves has something to do with it, "but chiefly, however, it consists of the sound that results from the muscular contraction of the ventricles." And he proceeds to say: "You are aware that the vigorous contraction of a large muscle is accompanied by audible sounds."

The teachings of this great pioneer of heart work have unfortunately developed into tradition and until recently this statement has not been challenged, but as Professor Halliburton mentions in his classic work on physiology, "A muscle when it contracts produces no sound." Old Dr. Maynwaringe, to whom I referred in my article on Notes on Phthisis which appeared in the January 2nd issue of JOURNAL writes in 1675 as follows: "It will not be lost time then but profitable to cast our eyes upon the practice of such writers as are accounted men of note, leaders in the profession, and see how they consent in this point and their reasons for what they do, because the age is much governed by tradition and example and think they are safe practisers, if they keep to the beaten road and if they have the authority of the predecessors to back them, and this is one main block that puts a stop to the proficiency and progress of this science, else it would have arrived to a greater perfection and certainty than as now it stands." How little do men alter during the course of the centuries!

As mentioned above, Watson emphasizes the sound associated with the contraction of the large

*From the American edition of Watson's lectures, 1845.

muscle, but what about the tiny muscular system which constitutes the fetal heart? To imagine this little organ producing a sound sufficiently loud to travel through the thick uterine walls as well as those of the abdomen is putting a strain on credulity. Fluid, on the other hand, can be demonstrated to produce a sound, for if a small quantity, say four c.c. of water be placed in a large rubber fingerstall, with its proximal end tied, and then rhythmically compressed with the forefinger, typical "heart sounds" will be conveyed to the ear by a stethoscope placed at the other end. "The short abrupt knock of chlorotic palpitations," Watson says, "is often attended with a bellows sound. The weak and flabby muscle dilates (I fancy) and the natural proportion between the chamber and its outlet is for a time destroyed." One can only add, *"mirabile dictu."*

Watson devotes much space to the head symptoms or "nervous disturbance which is so apt to occur in acute rheumatism," although these days we see very little of such disturbances. Osler speaks of four cases only out of three hundred sixty-five in which the patients had delirium and three of these he thought were due to, or aggravated by, the salicylates. In Watson's days those head cases were spoken of as metastasis to the brain. But he emphasizes the fact that in those the delirium had been extreme, no traces of disease have been discoverable within the skull. After quoting an interesting case in which the patient had become maniacal before death, he states that: "If no examination of the body had been made, the case might have been quoted as a well marked example of metastasis to the brain." It was so considered before the brain was inspected. The case occurred in 1824 and then follows this interesting paragraph. "Here had been symptoms which indicated the cardiac disease but at that time I did not know how frequently carditis was combined with acute rheumatism. Auscultation had not yet come much into fashion in this country; at any rate, I knew little or nothing of its use and I had supposed that the chest symptoms resulted from rheumatism of the intercostal muscles."

One hundred years ago auscultation was in its infancy and as Watson tells us had not come into fashion! Fashion in medicine! The mention of the word strikes oddly on our ears. Yet Maynwaringe, two hundred and fifty years ago, refers to, and soundly condemns, the same thing. Fashion in science fortunately does not seem to have arrived, though even here we meet with cults; orthodoxy is the great word today in medicine, and woe to him who thinks on independent lines, if by any chance such thinking disturbs the traditions of the fathers. It pays to be fashionable because *populus dult decipi.*

Watson points out that rheumatic carditis is sometimes the first step in the whole disease, the cardiac symptoms sometimes preceding those of the joint even by two or three days. This is a point to be emphasized, for the joint symptoms seem to be much less pronounced than they were thirty or forty years ago. Is it because people are better shod and better clad today, with the result that the joints are better protected and consequently less devitalized? Cold is the determining factor in the locating of extensive diapedesis known as chilblains, in those so predisposed, and it seems to me that with warmer clothing, the joints are not subjected in rheumatic fever to this accentuated diapedesis.

Watson's statement: "I know of no other exciting cause of acute rheumatism than exposure to cold, especially combined with moisture," is one that seems to have carried weight up to the present day. But while it may, as I have said, be the deciding factor as to which joint may be attacked, it can hardly be deemed sufficient to account for those cases where the carditis is the first evidence of the disease.

With regard to treatment, we may learn much from his failures. He tells us: "I once thought that if we caught the inflammation at its very commencement, we might calculate upon a perfect cure by first bleeding the patient freely, and secondly, by putting him under the specific influence of mercury." "We may easily deceive ourselves, for in a large number of cases, whether treated well, ill, or not at all, the patients seem to recover." "I am sorry to be obliged to say that the more I see of this formidable malady, the more reason I find for fearing that it is seldom within the possibility of repair."

How very true this statement of Watson's is today! How many patients are dosed beyond measure but without any good results especially as regard the heart. "Now," says Watson, "you may be sure when men's opinions concerning treatment of a disease, which is of common occurrence and easy recognition, are thus unsettled and diverse, you may be sure that no specific for that disease has yet been discovered; and secondly, that the disease is not very obedient to any remediable plan!"

Is it the disease or the patient's constitution that is disobedient? Is it not the tendency today to treat the constitution by stimulating its antibodies to rise in response to the injection of an autogenetic vaccine? We have reached the stage of recognizing the microorganism or the toxin. We just want a sure means of estimating the constitutional capacity in order to get the right response to a well ordered or well directed protein catalyst, injected so as to restore a disturbed time reaction to its normal periodicity. By this I mean that the important interchange between the leucocytes and the endothelial cells takes place within very definite limits as to time and that any disturbance of this time reaction results in disease. The exact location for the starting of this disturbance of the time reaction, as, for instance, in the vessels of the valves and myocardium, determines what we call carditis or acute rheumatism, while that which originates in the lungs gives rise to the exudation in which the ever present tubercle bacilli find a most desirable forcing soil.

But of bacilli, toxins and antitoxins, Watson knew nothing, yet his treatment of carditis was nearly as good as ours today, for we like him "are occasionally baffled and the patient continues to suffer notwithstanding the diligent enforcement of all the approved remedies and plans of treatment."

Watson was an optimist; his hope of success was based on his faith in medicine. "I am far, however," he tells us, "from thinking that remedies are useless and I do by no means assent to the dictum of Dr. Warren who, when asked what was good for acute rheumatism, answered six weeks."

A Psychohistorical Study of the Sex Balance in Greek Art*

L. PIERCE CLARK, M.D.,
and HERBERT R. CROSS, Ph.D.,
New York

(*Concluded from page 208*)

In later life such an individual completes his psychosexual union in love relationship, not with the opposite sex, but with someone who is more like himself and who better personifies himself; that is, his object love is unconsciously homosexual. If this unconscious trend is not sublimated or directed into acceptable social and personal channels he then becomes a potential candidate for a neurosis, as the state remains repressed or latent. We may finally summarize in saying that this tendency to a sex imbalance in ancient times, even as it is today, rests upon the psychobiological fact of the too prolonged and intensive primary identification of the child with the mother and the consequent imbalance of the psychosexual development of the child in later life incident thereto.

Although in many instances the homosexual neuroses as such are dispelled by psychoanalysis, the homosexual tendencies still remain; so that it may be questioned whether the psychobiological causes which induce homosexuality are really dynamic, whether the mother identification and its attendant autoerotism, or the later transformation of the identification into narcissism, is the real determiner of the overt sex inversion or its repression and later neurosis. Undoubtedly numerous cases which have now been successfully analyzed prove that this psychobiological process in the main is the correct one so far as a process may explain it, but is it really dynamic and fully causative for the state? If so, why doesn't inversion more frequently occur and when the analysis is quite complete why doesn't the inverted tendency fully disappear? Those who perhaps have taken a more static view of the inverted sex state may now put forward once more a purely biological explanation. In general terms the biologists maintain that the transmission of bisexual characters stand in the relationship somewhat as dominant and recessive characters in the Mendelian law of interitance so that the preponderance is in favor of the final sex to which the child is to belong. They argue that in some as yet unknown manner the mental character traits of the opposite sex in the child are the reasons why the mother identification is so strong and enduring, and that this biological inheritance is the real dynamic agent which sets in motion all that we have set forth psychobiologically as *the* reason for sex inversion. In short, biologists maintain that their principle is *the* dynamic one while the psychoanalytic formula but illustrates the manner *by which* this mechanism works. They point out further that the potential of the pattern engraved upon the somatic gametes predetermine the type of environmental appeal and stimuli to which the organism will give heed. They urge still further that all that psychoanalytic treatment may accomplish is to redirect the social values and conserve the individual from the neurosis of defective adaptation consequent to his inverted sexual character; that the real and underlying biological evidence of inversion *per se* remains quite unchanged throughout the life of such an individual.

While psychoanalysis may pride itself upon a practical cure of inestimable worth in a homosexual neurosis, there still remain other problems to conquer which as yet lie outside an immediate psychoanalytic therapy. I may refer incidentally to the social significance of the whole sex imbalance mechanism as seen in everyday life independent of homosexuality *per se* or its neuroses, and which lie at the foundation of the ordinary types of marital unhappiness. Here even abnormal psychology throws a flood of light where other methods of investigation leave the subject in obscure mystery. For instance, in marital infelicity what is more common than to find that the egoistic attitude, the fiction ideal or personal ambition of one mate is in jarring discord with that of the other? This type of marital difficulty is most frequently stated in legal phraseology as "incompatibility of temperament." Many other factors aside from the egoistic ones are, of course, at fault, but we submit that by and large the fundamental one is in the defect of ego adaptation; not, perhaps, in its crassest form of simple egotistical selfishness—as loose a scientific phrase as this may be—but in the more subtle continuance of the inadaptive narcissism of the contracting parties in the marital union. As yet these slighter but more subtle forms of defects of egoistic adaptation have hardly been touched upon in scientific analysis. The field as yet remains almost entirely in the hands of the dramatist, the novelist, and the poet.

It is even our obvious duty as physicians to subject these more subtle patterns of social and economic defects to analysis as well as to the specific medical pathology which until now we have mainly directed our efforts. As an earnest of meeting this need perhaps one might not do better than to analyze in a general manner a historical epoch itself and lay in parallel columns, as it were, the social traits of the life of that period with those depicted in its art ideals. The art representation may be said to mirror the varying transformation of the collective life of the people as a whole. If such an analysis should be in direct accord with what we know of that social and economic period, its origin, rise and decadence, we may infer that the analysis of the life of that period is true. Furthermore, if it is proved that the dynamism of the love life of a people as thus portrayed is a true explanation or foreshadowing of its changing culture, such a study will be of inestimable value in understanding the rise and fall of cultures and therefore be of greatest biological significance to all civilized peoples.

*Presented before Historical Section, New York Academy of Medicine, November 30, 1923.

GENERAL REMARKS.

For general purposes it does not matter whether one takes the stand that homosexuality is the main cause of the peculiar sex balance in Greek art, but for scientific study it is important to know how this blending of the sex characters in one and the same subject has arisen. It is highly essential to recognize that this art tendency is but the unconscious projection of the sex ideals of the time. There can be no real doubt that the tendency of this ideal was first a fine restraint of homosexuality, the undue subordination of the opposite sex characteristics to that of the main character of the dominant. Such a restraint is altogether praiseworthy and had much to do, no doubt, with the all roundness of developmental life of the period. Indeed, it lies at the very heart of all proper development in any and all periods. It is only in recent times, indeed in our very own day, that this factor in complete development has been made clearer by psychoanalytic investigation. Heretofore the matter rested upon the somewhat static formulation that the unequal dominance of one type of characters was due to the uncertain and anomalous taking over of certain elements of the one type of parent at the expense of the other and that the series of life experiencs which the individual child underwent played little or no rôle in the after life. We now see, though this biological explanation may be the predisposing and therefore controlling determinant of the manner in which the individual child shall make his adaptations, the psychobiological principles of mother identification give us a more flexible explanation of how this sex anomaly comes about. The why of it is as inexplicable whether one takes the biological or the psychological formulation. The union of the two dynamic factors, as has been already urged, is perhaps the wiser view to take at present. Not to do so lands one sooner or later into the quagmire of all sorts of sophistications and rationalizations. Psychologists need to know more biology, and *vice versa*.

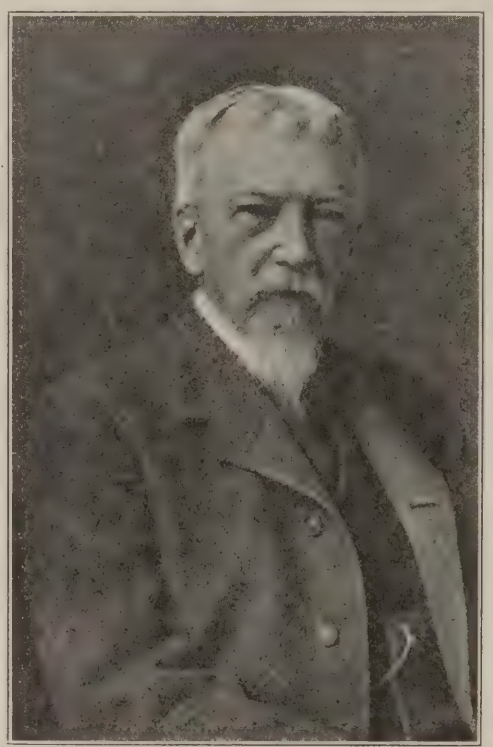
Turning to the more immediate issues in the study, why should the boy object of love in Greek life and art have been inferior? Can love only occur between unequals? These are quite as germane questions in heterosexual as in homosexual love. One may justly question whether the inferiority is real or fictitious. We know that love in its essence consists in an identification with the loved object. It is, as Burrow aptly expresses it, seeing oneself in another, the recognition in another of that which one would himself be. To love, then, is more than an appreciation but is to find in an individual an unconsciously cherished image of oneself, to realize one's ideal. Love, therefore, is an unconscious process. The seeming inferiority which the onlooker may feel in all love than for the *lover* really does not exist. Just in proportion as this primary identification with the mother endures, the individual child remains infantile because it is, itself, born of that period and state. It also remains largely affective because it is closely bound up with the intuitive feeling of the feminine nature. Likewise to the extent of the two foregoing propositions, the child in development remains introverted in tendency.

We have long known that in man's ancient past in his primitive state that though a deep and unconscious transference of his soul energy to the realities about him (which we call the object in contrast to man's subjective individual self), there is something of the awful and terrible infused in the several objects of his environment. In the Greek period this was called the fabled Dionysian attitude expressed in unbridled frenzy, fury or freedom of attitude and behavior; these mythological forces we now know are emanations from the deeper unconscious forces of life. In contrast to this we had a more superficial mental attribute, the creative power of art, music and painting, in short art which was born by an inner contemplation of the idealism of one's own soul. This more adaptable mechanism of directed effort of man was supposed to be presided over by Apollo, the soul of the art functions. The aesthetic function of art was thus the energy of the deeper and archaic power flowing up through the conscious repressive screen and appearing in a state acceptable to consciousness as creative art. It has all the magic beauty of the soul's idealism but the awfulness of the Dionysian orgies was repressed. Thus we had in the Greeks a projected art drawn from the soul's highest and loftiest idealism. It literally charmed man's mind from the awfulness of the writhing fury his deeper nature might otherwise have enmeshed him. It was usually in a state of nakedness. It portrayed a state of introspection, of inner contemplation toward the dream or phantasy world of eternal ideas. It was essentially an aesthetic attitude of portrayal but one of the many essential attributes of the real human soul. It did not rest essentially upon the whole life of a people before and after death, hence it was not as fundamentally great in concept as that of the less graceful and intrinsically less form of beauty of the Egyptians that preceded it. A part of the poise and serenity of Greek art is due to this very aesthetic contemplation which is so largely drawn from an idealism that is so static and oftentimes essentially aloof from reality, even being beautiful at the expense of being unreal. It is easy to see also that in this portrayal of an inner idealism that the bisexual phase would naturally have representation. May not this be explained by the fact that a certain high degree of oneness and unity exists; where the two sex natures coequally exist in the one individual to such a high degree, and just in proportion as the two sex characteristics have the opportunity to function colligatively, that individual will be sufficient to himself. While this explanation has its limitations, one may easily find many examples wherein certain natures have such a wide reach of satisfaction within the range of their own life interests and work that the need of an outside supplement may be negligible. Finally, the Greeks being able to hold in leash, to repress the homosexual tendency, or rather to sublimate it in manly or normal human service, was the great lesson taught us in their early life ideals. As the civic and social fabric deteriorated, even as in the less heroic days of our own time, this restraint and sublimination failed, and debauchery and vice changed places with strength, vigor, and sobriety of living.

Contributors to the Science of Medicine

S. WEIR MITCHELL, M.D., LL.D., F.R.S

Silas Weir Mitchell was born in Philadelphia in 1829. His father, John K. Mitchell, also a physician of note, was a member of a Scotch family that had come to Virginia to settle. His grandfather was the Mitchell who gave Robert Burns, the poet, the position by means of which he made a living. An autobiographical note of Weir Mitchell's states that his father once said to him: "You are wanting in nearly all the qualities that go to make success in medicine. You have brains enough, but no industry." Mitchell himself added, "He was correct. I developed late." Another note reads: "Surgery, which was my father's desire for me, was horrible to me. I fainted so often at operations that I began to despair—but by assisting at the surgical clinics I overcame by degrees my horror of blood and pain." In spite of such experiences, Mitchell persevered, studied medicine at Jefferson College, from which he was graduated in 1850, afterwards doing work in analytical chemistry in a drug store. He later went to Paris, where he continued his medical and surgical courses.



S. Weir Mitchell

For ten years after his return from abroad, Mitchell devoted himself to a not too urgent general practice, which gave him time for experimental investigations in physiology, pharmacology, and toxicology. He was the first notable example in the United States of medical success based upon what we now call laboratory work—there were no medical laboratories in America then. Before 1863 he had published a number of papers and reports on various phases of the subjects mentioned above, the most valuable of these probably having been the monograph on rattlesnake venom, issued in 1860 as one of the Smithsonian *Contributions*. After 1863, his most important researches were along neurophysiological lines, his most notable contributions being those on the cerebellum. For that year was the turning point in his career toward neurology. Mitchell and George R. Morehouse were at this time placed in charge of a military hospital for nervous diseases. From this time on, the former, sometimes collaborating with his assistant, young William W. Keen, issued a series of brilliant papers on such subjects as reflex paralysis, gunshot wounds and other injuries of the nerves, malingering, antagonism of morphine and atropine and other subjects. In 1872 these and other papers were gathered and published in a volume entitled *Injuries of Nerves and Their Consequences*. A valuable addition was later made to this by his son, Dr. John K. Mitchell, in the form of a supplementary volume giving subsequent histories of surviving patients and additional case material. Dr. William H. Welch writes that "the study and description of peripheral nerve phenomena, especially those resulting from injury, constitute the largest, most original, distinctive, and important contribution of Weir Mitchell to neurology, and in this narrower field his work is comparable to that of Duchenne and Charcot upon diseases of the spinal cord."

After the war Mitchell rapidly gained and held the position of leading neurologist in this country and one of the most notable in the world. His chief institutional work was done at the Orthopedic Hospital, where he was instrumental in establishing in 1870 the Infirmary for Nervous Diseases. Here he taught, worked, and surrounded himself with a school of the ablest investigators and clinicians. Among his discoveries and original observations were postparalytic chorea, erythromelalgia, reflex disorders due to eyestrain, the unilateral hard edema of hysterical hemiplegia, and the relation of pain to weather. Other contributions are on the early history of instrumental precision in medicine, recollections of the Civil War, his papers on Harvey, whom he admired above all men, his personal memoirs, and his delightful popular talks. His many stories and novels give evidence of his large and sympathetic experience of life as a physician, and some of them deal with or introduce distinctly medical subject matter, as, for instance, *Doctor North and His Friends*, the *Autobiography of a Quack*, the *Case of George Dedlow*—the story of man who lost all four limbs—*Hygh Wynne*, and *Circumstance*, both describing senile change; *Roland Blake*, involving hysteria; *Far in the Forest*, a story of paranoia; *In War Time* and *Constance Trescott*, both describing moral deterioration of character. "But he emerges from his own hard early struggle and his long experience of human excrescences," writes Owen Wister, relative and friend, "writing the literature of encourage-

ment, not discouragement. No matter through what dark alleys his muse passed, she comes to us always with her skirts clean and her heart warm. She wishes us well, not ill; she gives no sneer at the evil world, she is sorry for it; her gospel is not of hate but of love. The tone of Mitchell's books is a lesson and a tonic for an age that is sick and weak with literary perverts."

Mitchell was also a writer of poetry of unusual merit and in some cases of rare beauty. All his writings, both literary and medical, possess a noteworthy charm and forcefulness of style. His scientific and literary ability persisted to the very end of his long life; it is interesting to note that his last novel, *Westways,* was written at the age of eighty-five. One of his distinctive characteristics was always to give very pointedly descriptive titles to his productions, even those of a scientific nature. He did not call an important article "Interesting Cases" to the despair of the researcher worker, but *Backward Pronunciation of Words,* or *Lip Whispering of the Insane.*

Weir Mitchell held many positions of prominence during his long and active life, and was the recipient of many notable honors, both in his native land and abroad. He was a member of the Academy of Natural Sciences, a Fellow of the College of Physicians of Philadelphia, a foreign associate of the French Academy of Medicine, of the Royal Society, and of other foreign bodies. He held an honorary degree of M.D. from the University of Bologna and an LL.D. from Edinburgh.

Probably his greatest fame with the public, however, and with many of his own profession, rests upon the fact that he originated and practiced the method of treatment that bears his name. This is too well known to need comment here.

No more beautiful tribute has ever been given to Weir Mitchell than that in the address of Dr. Welch at the special memorial meeting of the College of Physicians of Philadelphia held soon after the great neurologist's death on January 6th, 1914. Welch said: "He was a great physician; our leader, endeared and admired; our friend and counselor, generous, wise, inspiring; a man of singular graces and accomplishments, active in advancing knowledge and in good works; a poet and a man of letters; a sweetener of life to both sick and well. As he said of Harvey, we may say of him—Weir Mitchell represented all that is best in the physician and the gentleman."

Hookworm Disease.—If the references contained in the Ebers papyrus really refer to hookworm disease, they would make the knowledge of the disease very ancient. . . . Dubini, in 1838, first described the worm and gave the name from the bent or curved appearance of the mouth. In the latter part of the nineteenth century, the anemia of brickworkers in Italy was shown to be due to a parasite, but it was not until the investigations of Stiles in 1901 and later that it was shown that the hookworm was widely prevalent and responsible for a vast amount of ill health and anemia.—*Proceedings, Medical Association of the Isthmian Canal Zone.*

Louis Daniel Beauperthuy.—Casey A. Wood M.D., *(Annals of Medical History,* June, 1922) gives an account of the life and work of this original investigator and authority on epidemic and endemic diseases and leprosy. Beauperthuy was born in 1803 in Guadaloupe, and took his M.D. degree at Paris in 1837. After graduation he returned to Guadaloupe to practise and especially to study tropical diseases. Quotations from his writings are given, describing some of his discoveries and opinions. The absence of mosquitoes during cold weather, he states, explains the disappearance of malaria. It is not the decomposition of water that makes it dangerous to health and life, but the presence of these insects. During the dry season fevers of all sorts diminish or disappear, but they revive during the rainy seasons, when mosquitoes are numerous, and the diseases they produce are then most malignant. Beauperthuy goes on to say that the mosquito is responsible also for yellow fever and various other diseases. He states his case emphatically and just as definitely denies the truth of the older medical theories, although it remained for others to establish the exact nature and origin of the virus. He asserts many times that mosquitoes and other insects alone are the causes of such fevers by inoculating their victims with poisons.

Beauperthuy is mistaken, however, as to the nature of the morbidic agent, which we now know is a live organism transferred by the insects from man to man, and not, as he conceived it, an extraneous substance ,such as ptomaines of putrid fish. Boyce recognized in Beauperthuy "a medical man with a strong biological trend," and calls him "the father of the doctrine of insect borne disease."

He was also an ardent investigator of the cause and nature of leprosy, which he thought might too be propagated by insects. His socalled cure of the disease was practised in North America, Europe and India, and his services were in wide demand in the West Indies and South America. He did not profess to cure nor did he wish to treat advanced cases of leprosy, but only those in their incipiency. His system of treatment included residence in as salubrious a locality as possible; a diet, nutritious but not over stimulating, consisting of a daily portion of fresh meat, but no pork nor salt fish; red wine in moderation if the patient had been accustomed to it; and, in addition, attention to the other rules of personal hygiene.

For internal treatment he gave mercuric bichloride in small doses. Certain liniments were used to relieve and cure the eczematous and other eruptions. For active destruction of the tubercles, he employed either a strong solution of silver and copper nitrate, or, perferably, the oil of the cashew nut. Subsequent observers, the writer states, while reporting amelioration of the symptoms in some cases, reported against the treatment as a whole. No cases of permanent cure were reported, but in its day the Beauperthuy method was employed in many countries of the globe.

Beauperthuy died quite suddenly in 1871 of apoplexy at the leper establishment on Kaow Island, where he was engaged in developing his system, his services having been sought by the government of British Guiana.

Editorial Articles

DISINFECTION OF THE URINARY TRACT

There is considerable difference of opinion regarding the effectiveness of disinfectants administered internally, particularly intestinal disinfectants. So far as urinary disinfectants are concerned, there seems to be general agreement that given favorable conditions and in certain circumstances urine may be disinfected in a very satisfactory manner. For example, it is admitted that hexamine will give good results in this direction when conditions are such as to give full play to its disinfecting properties. Many authorities have stated conclusively that it is an invaluable urinary antiseptic. Being excreted by the kidney, it is split up in the acid urine, free formaldehyde being liberated, which destroys the germs in the secretion. But in order that the drug shall exert its disinfecting action, the urine must be acid.

In a recent number of *Deutsche medizinische Wochenschrift* is an article by G. Daniel on the treatment of pyelitis by hexamine which is better known by the name of urotropin. It is pointed out that apart from secondary infections of the renal pelvis, most cases of pyelitis are due to infection with the colon bacillus. The growth of this bacillus is checked by urotropin in acid urine, and activity of growth of the colon bacillus is inversely proportional to the concentration of the urine. On the basis of these observations, a system has been adopted, the chief features of which are the reduction of fluids and the administration of an acid forming diet, with phosphoric acid, urotropin, salicylic preparations and, further to concentrate the urine, diaphoretic treatment. Under this form of treatment the patient excretes concentrated acid urine, and the quantity being reduced, micturition becomes less frequent. Moreover, the urine being retained in the bladder for a considerable time the opportunities for its disinfecting the structures with which it comes into contact are increased. According to the writer, the results of this mode of treatment have been excellent, fever, pain, pyuria, and frequency of micturition disappearing, and the urine becoming sterile. The writer states that since 1917 he has practised a modified form of this treatment at the University Hospital in Budapest with definitely good success in almost all cases. The details of his methods of treatment and the results are given in his article.

It may be pointed out that in many chronic diseases, the socalled rheumatic group for instance, it is essential for success that free diuresis be induced and that the urine be disinfected and detoxicated as far as is possible. The belief is current, and appears to be gaining greater currency, that most of the chronic diseases are of toxic origin. These toxins, according to the views of some authorities, are generated in the intestines by reason of long continued intestinal stasis and in course of time pervade and permeate the whole system, and in this poisoning, of course, the urinary tract is involved.

While the effects of prolonged constipation and chronic intestinal stasis may be exaggerated it is reasonable to believe that in this manner toxins may invade the system to such an extent that diseases and conditions of ill health may ensue. In any event, it is always indicated to maintain the functions of excretion and elimination in good working order and to combat pyelitis, cystitis and other symptoms showing that the machinery of the body is out of gear by disinfecting the urinary tract by the most effective means at our disposal.

THE INTOXICATION OF SPECIALIZATION

Specialization has its purposes. When the general practitioner has reached an *impasse* he is glad to refer his case to the specialist. And this tendency to specialize is so acute, especially in the large centres of civilization, that we hear rash statements to the effect that the general practitioner is obsolescent. Not so! In every community from Key West to Nome he still bears aloft the standard of humanity and healing. And that wit who said that So and So specialized in the "skin and its contents" unconsciously described many a local Paracelsus. By the sheer exigency of circumstance thousands of physicians spend a long and useful life curing malaria, pulling teeth, taking out appendices, intubating, vaccinating, and, it may be added, advising, encouraging and shriving whole communities.

But with it all, the specialist has his place, and a necessary one. The demand for him is, of course, greatest in the large cities, and the physicians graduating there naturally look forward to specializing later in their career. The young doctor, we will say, has a penchant for neurology. He makes the highest mark in the medical school examination; he reads Jelliffe and White, and Freud and Jung and Adler, and Hunt and Bing, and Church and Pedersen, and so on. He finds a few cases of psychoneurosis in his practice, and is able to relieve them by psychotherapeutic means. He joins the local neurological society; and, finally, when he has in the natural

course of events attained to that appearance of approaching senility which alone will convince the average layman of a right to specialize, he abandons his general practice, except of course those old patients and family friends who still believe in him and will have no one else—as long as he continues to treat them at reduced rates.

Now this is all very well, and quite natural and proper. But there is a danger. Just as the tailor sees everywhere fits and misfits and the literary censor pornography in every printed page, so does the specialist see his specialty. He becomes intoxicated with it. And in so doing he is bound to suffer occasionally from the scotoma inseparable from any form of intoxication. He misses clinical signs which are obvious to the general practitioner, and he lays undue stress upon those which point to his own specialty.

The remedy is twofold. One strand lies in the hands of the general practitioner who should only refer a case to a specialist—short, of course, of some urgency where delay might prove serious—when he is sure the patient has some disorder within that specialist's province. And the second string belongs to the specialist himself. Having obtained an all round medical education in the medical school itself, he should determine to lay a broad general foundation in actual practice before attempting a specialty. The ideal way would be to spend at least five years at it, and every physician, for the good of his soul, should practise for one year in a rural community.

Then he is perhaps ready to specialize, for in his system are circulating those antitoxins of general medical knowledge and experience of the organism as a whole, which are the best protection against the intoxication of specialization.

THE QUESTION OF BIRTH CONTROL

Opinions expressed with regard to birth control differ widely. In civilized countries and among the well to do it is practised frequently. Some medical men are noncommittal on the subject. In Great Britain a section of the profession, including several well known men, have declared themselves in favor of contraception generally with certain reservations. Some of these gave their views in the *Practitioner* of last June. Recently, Dr. Mary Scharlieb, one of the best known and most experienced of the British female practitioners, stated in public her ideas on the subject. She pointed out that this was essentially a material age and that birth control was largely an affair of selfishness on the part of both wife and husband. Dr. Scharlieb scouted the excuse brought forward by some people for not having a family, that they were afraid of transmitting hereditary or transmissible disease. This view is largely a bogey. Inherited diseases were few, and the chief of them would not exist were it not for hopeless materialism and selfishness. Artificial control is useless and by engendering false confidence frequently leads to the transmission of the very diseases that its advocates plead it is calculated to avoid. There are a certain number of young married folk who think it smart not to have a family at once. But people who put off the responsibility might find that they could not undertake it when they were willing. As for the purely medical aspect of the subject, she had been in practice for forty-five years and she knew that women who shirked their duties as mothers suffered often from nerves and lost a great deal of the joy and spring of life.

There were methods frequently practised which were specially harmful to the nervous system of the husband, others which fell with greater severity on the wife, and yet others that were injurious to both. Moreover, she knew that it was practically impossible for most of these arrangements to be effected decently and comfortably and that often they were not effective. As a doctor, therefore, she condemned all artificial control of conception as being injurious certainly to the nervous system, sometimes locally undesirable, and occasionally leading to serious illness, or even to death. Also as a doctor she knew that the increasing propaganda with regard to artificial methods of control was exceedingly bad for the unmarried of both sexes. A large number of people who meant well required the support of public opinion in order to enable them to do well, and the advocacy of nauseous practices was a great injustice to weaker brothers and sisters. This is the most severe indictment of birth control which has been made publicly by an authority and is deserving of earnest consideration. Doubtless there are economic reasons why limitation of births is highly desirable. Overpopulation is one reason and in spite of the assertion that there is plenty of room in other countries for the surplus, the fact is that the authorities in other countries will not take many of the surplus population who are willing to go and which their own country is only too willing to get rid of.

Large families, as a rule, are most frequent among those who are least able to care for their children and bring them up properly. On the other hand, birth control is most common among those who are able to rear their children in a healthy environment and educate them to become useful members of society. It is obvious that a great many women have too many children, and it is women who have to work hard and who have little time to spare for the care of their children who have usually the big-

gest families. It would appear then that in some instances birth control is justified, as it cannot be in the best interests of the race, nation or individual that children should be brought into the world whose parents cannot house, feed, educate or care for them in any way properly. Such children are apt to become a burden and a menace to the community than a help.

The strongest argument, however, that Dr. Scharlieb brings against birth control is that all methods of artificial contraception are injurious in themselves and often ineffective. There is a great deal to be learned concerning birth control before it is unduly praised or wholly condemned. One point about it seems certain, that if it is done for material and selfish reasons it is to be condemned, and another point is that if it is a means of limiting the output of the fit while no limitation is placed on the propagation of the unfit or relatively unfit or of those whose parents cannot bring their offspring up properly, it is to be condemned.

THE TREND OF MEDICINE IN GREAT BRITAIN.

In Great Britain a crisis in the fortunes of medicine appears to be approaching and with some celerity. The passing of the Insurance Act, with the institution of what is generally known as panel practice, introduced drastic changes into English medical practice and was the thin end of the wedge towards the introduction of further and more sweeping reforms. The establishment of a Ministry of Health was the next move in the direction of more changes and the latest report of Sir George Newman, chief medical advisor to the Ministry of Health entitled Recent Advances of Medical Education in England is, to some extent, an exposition of the medical situation and predictions as to the future from the point of view of the State.

Sir George Newman, in addition to being an authority on public health and hygiene, is a facile writer of great distinction. His literary gifts equal his knowledge of health and medical affairs and his capacity for organization. He expresses himself logically and lucidly and with broad statesmanlike views. His phrasing is so picturesque that he makes of what in some hands would be a dry as dust document, a real romance of medicine. He lays stress on the fact that the purpose of the new medical curriculum, which has just been revised and approved by the General Medical Council, will bring forth practical results. Of course it has been obvious for some little time that the trend of medicine is towards prevention and this trend necessitates changes in the medical curriculum.

Sir Clifford Allbutt said in 1919 that medicine had come to a new birth, and Sir James Mackenzie has been preaching both by theory and practice that preventive treatment does not consist only in preventing disease by public health measures, hygiene, domestic and otherwise, and so on, but by treating the early symptoms of disease in such a way that it is prevented from developing. But in order that this same method of prevention may be possible the public must be educated to consult a medical man when early symptoms appear, and the doctor must be taught to diagnose and treat successfully early symptoms and even when disease has developed, to diagnose the original cause and not the surface symptoms, and treat accordingly.

With the education of the public the report does not deal. It is, however, pointed out that the medical student must learn how disease begins and why, and what the first symptoms are. If he is not thus educated he will not be fully equipped for the modern practice of medicine, whether he is to be a private practitioner or a public health doctor, as the community both as taxpayers and patients are intimately interested in his efficiency and in his thorough training for his somewhat new rôle.

Sir George Newman insists that, while the new medical curriculum and the public health rules "give added emphasis to the application of science to the clinical aspects of medical education, the inspiration of reform has been the prevention of disease . . . obviously curative medicine and remedial surgery must have immediate priority, but the ultimate goal is prevention."

In the report it is demonstrated that the private medical practitioner is really to be looked upon as an outpost of the national organization of State medicine. The following paragraph culled from the report shows that State medicine in England has made already a considerable amount of progress.

"Two million children are inspected every year, and all children, healthy or sick, are now under medical supervision in school or at school clinics. Similarly, the Public Health Service has been concerned in dealing with early cases of infectious disease, infancy and child welfare, and with the establishment of tuberculosis and venereal disease clinics for dealing with cases of these diseases. Under the National Insurance Act, thirteen million persons are entitled to medical advice when they begin to ail. In the medical schools, too, there has been an immense development in the use of outpatient departments and children's clinics at hospitals, and there has been a wide movement in favor of the study of disease in its earliest stages. This is all to the good. But the student must be brought into it.

Indeed, the entire report is intended to show that

in the new curricula, which have been introduced, preventive medicine, dentistry and public health are of the first importance, and that, in fact, preventive medicine is doing much good now and is rapidly developing into the medicine of the future. As the practice of modern medicine is being revolutionized, so will medical education have to be revolutionized to keep pace with its developments.

The author of this eloquently phrased plea for preventive medicine ends by suggesting that Great Britain may well serve as an international centre and clearing house for the world and pays the following tribute to this country. "Some of the medical schools of the United States are better equipped than anything there is in England and this gives them larger facilities for internship, for private and special wards, for laboratory work, for the keeping of records, and for research; their students are usually senior to ours in age and learning; their total course of training is generally longer; and in certain departments of surgery they claim to be ahead of us. We have much to learn from their vision and capacity."

The report certainly does show that medicine is being reborn in Great Britain, that is, that the character of medical practice is undergoing a radical change. While it is undoubtedly satisfactory and encouraging that disease should be prevented rather than cured, and while it is obvious that with this end in view medical education must undergo a change, the report also reveals another point which to the medical practitioner is by no means so pleasing. It reveals the fact that in England not only has the State already gained some control over the medical profession but that this control is increasing. Will this control eventually lead to nationalization of medicine, a result so eagerly advocated by the labor party? This party represented by the Associated Societies at the present time wields a great deal of influence over the doctors practising under the Insurance Act, because the majority of the patients belong to these societies. Moreover, these societies seem anxious now to demonstrate their power. If the labor party makes use of their political power to attempt to force nationalization of medicine, what will happen? Are the majority of the British medical profession in favor of it or not? It seems that this is the question which may be put before medical men of Great Britain in the future.

The report of Sir George Newman affords evidence that the character of the practice of medicine in England is changing and also that the State is assuming control and supervision over a considerable portion of the profession. Whither is it leading and where will it end? There is no doubt that American medical readers will watch events concerned with medicine in Great Britain with keen interest as it touches them closely. In any case Sir George Newman may be highly congratulated on having produced in the most recent report a masterpiece in its way. He can also point with legitimate and justifiable pride to the results which have proceeded already from putting into practice the tenets of preventive medicine and especially, perhaps, to the outcome from the inspection of school children. So far as it has gone in England modern preventive medicine has abundantly proved its value.

WHAT IS PHYSICAL EDUCATION?

Every war, doubtless from the first of them, has been accompanied and followed by lamentations over the scarcity of men of the first fitness for fighting. These lamentations have, in numerous instances, ancient and modern, been followed up with efforts at improving the health and physique of the rising generation along lines which, at the time, seemed suitable to produce the desired results. The suggestions of the need for physical education made by great thinkers, such as John Locke, Pestalozzi, Rousseau and Spencer, who had the welfare of the individual child at heart, have usually fallen upon deaf ears; but when the need for cannon fodder was felt and expressed by statesmen or warriors, attention has been given and something has been done to remedy the situation, even if it was ephemeral and useless.

Legislation for physical education in the public schools which has been successful in some thirty or more states (though it had been put in practice in but few of these) was the result of the war and not of the demand for such laws on the part of educators, although the latter recognized, in a feeble way, that physical education is at the root of all education and that the effectiveness and the economical working of the machinery for mental training depend on the bodily condition of the child with which it deals.

There was such a spasm of encouragement of physical development at the time of the Civil War, military drill being considered the best means for such development, and the influence of this movement still survives. There was a similar selfexamination for causes of poor physique and searching for means of improvement in England, following the Boer War. The Swedish system of gymnastics was chosen as the best method for muscular exercise, but the committee of investigation had the good sense to observe that, for a very large number of the children of the realm, not exercise but feeding was most needed and that the former without the latter would do more harm than good. Probably this was the most notable pronouncement in physical education

that has occurred, as it was the first official recognition that our attempt at a maximum unfolding of the physical nature of the child must be put upon the basis of adequate nutrition. Before that time everything in physical training was exercise; now it must be feeding, rest—then exercise. Our present nutritional work in schools may not have had its origin in this report of the British Committee, but it follows along the same line.

We have mentioned the Swedish System of gymnastics. This and the methods devised by Jahn and his followers in Germany and the systems which arose in other European countries all had a patriotic stimulus at the bottom of them and, while accepted by schools, had an eye to the furnishing of material for the army.

All these methods, ingenious as they were, failed to develop one hundred per cent. perfect men, and, though formal training in physical training exercises had gone on for a hundred or so years, the number of those imperfect for military purposes was about as great as it was in countries where no such training had been in progress.

In passing laws and arranging courses in physical education in our own land in the twentieth century there have been inherited in many quarters the tradition that physical education means only exercise. It it most unfortunate, for exercise has long been tried and found wanting, in itself, to cure our bodily faults or to develop our somatic possibilities. There is considerable in a name sometimes, and in the present case it means very much to the cause of physical education that the term should be considered as including every means, prenatal and postnatal, in the home, in the school and elsewhere, that can be brought to bear to make possible the bodily unfolding of the child.

It means, above all things, ample animal nutrition, rest, and fresh air; it includes the removal of physical handicaps that can be removed, protection against infections, and a hygienic atmosphere at home, at school, and in the community as a whole.

Physical educators, if they would have their wares properly evaluated in future, should be careful not to use a general term for the part, and not to present the public with athletics, or gymnastics, or medical inspection, under the name of physical education.

Even as a whole physical education is greatly limited as to what it can accomplish, for, through all its agencies combined it can hardly eliminate more than a fraction of the defects displayed by the draft, for a very large proportion of these are a part of our human and animal inheritance and are likely to appear (unless the eugenists can save the day) in the draft for the wars of the year 3000.

MOTHER AND CHILD WELFARE IN PALESTINE

A widespread and dire need for maternity and child welfare work in the Holy Land is being met by the Hadassah Medical Organization which is developing a complete system of infant welfare stations in Jerusalem and Tiberias, according to a recent report. The work is being financed through private donations and collections from organizations interested in the plan. The Hadassah Medical Organization has already done a great deal of active work in the region. In 1921, an infant welfare clinic was established in the old city of Jerusalem, affording to mothers in Palestine the first opportunity of receiving instruction and advice as to caring for their children in good health. The clinic was so well patronized that in less than two months it was necessary to open a second consultation centre, this time outside the city walls. The report goes on to say that, during nearly all of the first six months, the only assistance the doctors were able to have was that of volunteers from a women's organization in Jerusalem. There were no nurses, and only patent milk preparations were available. So a milk kitchen was established and equipped, two consultation centres, with nurses and doctors, opened, the "donkey milk express" started, and the work gradually extended to Jaffa and Haifa. Among the nationalities of the mothers frequenting the clinics were those of Persia, Arabia, Morocco, Turkey, Bakhara, and of course Palestine, and some from the nations of Europe and from America. In 1922, a large private donation enabled the Hadassah Medical Organization to establish a separate consultation clinic for Arab mothers and to employ an Arab speaking nurse, who is a graduate of a nurses' training school.

FOREIGN PUBLIC HEALTH OFFICIALS IN ALBANY

The worldwide and rapidly growing interest in public health matters received significant attestation in the recent visit to the New York State Health Department of the delegation of eminent foreign officials forming a part of the third international exchange of health officers arranged by the Health Section of the League of Nations at the invitation of the United States Public Health Service. The delegation as a whole was divided into three groups for the purpose of studying American administrative methods in public health. One group was sent to North Carolina and later came to New York, another visited Virginia and Massachusetts, and the third, Alabama and Pennsylvania. All three united for conferences at Washington and Johns Hopkins, and New York. The group that visited the State Department at Albany spent a week in that city. They studied administrative methods and problems of rural hygiene and municipal sanitation, visited the Bureau of Municipal Information, and the radio station that broadcasts the weekly health talks. The delegation included representatives from Poland, Holland, Germany, Chile, Russia, Mexico, and the Ukraine. The final report of their visit will be made to the Health Section of the League of Nations at Geneva.

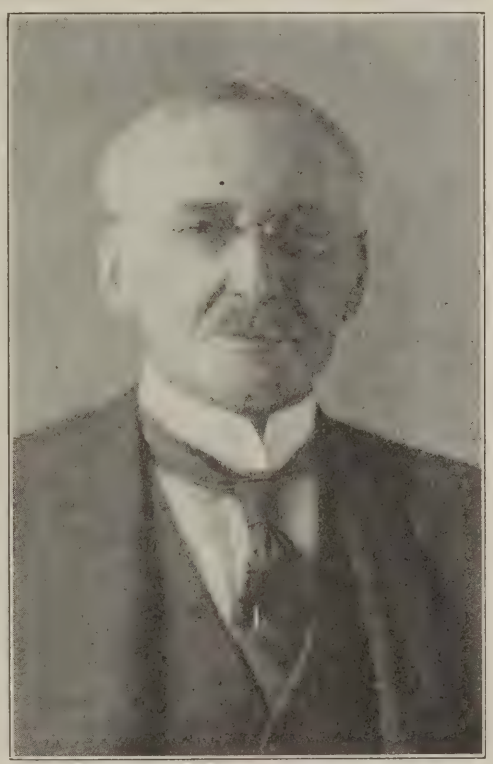
Obituary.

JACQUES LOEB, M.D., Ph.D.

New York.

Dr. Jacques Loeb, one of the leading scientists of the day, died on February 11, 1924, at Hamilton, Bermuda, during his annual visit to his marine experimental laboratory. His illness, from heart trouble, was of brief duration. The funeral services, which were private, were held on Sunday, February 17th, at the Rockefeller Institute for Medical Research, New York City, where Dr. Loeb had held since 1910 the position of head of the division of experimental biology.

Dr. Loeb was born in Germany in 1859. He studied medicine at Berlin, Munich and Strassburg, receiving his degree of M.D. from the University of Strassburg in 1884. After teaching biology and physiology in the Universities of Würzburg and Strassburg for several years, he came to the United States and was successively professor of these subjects at Bryn Mawr, the University of Chicago, and the University of California. In 1891 he married Miss Anne Leonard, of Easthampton, Mass.



JACQUES LOEB

While at the Rockefeller Institute, Loeb was a brilliant investigator in many branches of physiology, but his most characteristic work was done along the lines of the dynamic or chemodynamic theory of living processes. In his work on the physiology of the brain, he made original researches on the chain reflexes, and overthrew the position of Munk that the Rolandic area is made up of cellular sensory spheres by showing that the paralysis occasioned by each cortical excision will be abolished as soon as healing of the wound takes place. He was one of the first to settle the question of what order of magnitude is the smallest particle that can show all the phenomena of life, and his experiments on temperature coefficients established important criteria of physiological processes.

He made extensive investigations into the effects of electrolytic, thermal, and radiant energy upon living matter, and founded the theory of tropisms as the basis of the psychology of the lower forms of life. Even for the higher forms, he conceived all actions of fundamental importance as instinctive and having no relation to states of consciousness, and even these he believed might have a chemical basis. In 1889 he caused unfertilized sea urchin eggs to develop into swimming larvæ through treatment with hypertonic sea water. He carried his experiments farther by a preliminary treatment with butyric acid, producing an artificial fertilization membrane with complete development, following immersion of the eggs in a hypertonic solution before returning them to normal sea water. He showed further that the ovum has a selective, specific activating influence on the spermatozoon. In 1916 he reported raising several male parthenogenetic frogs to the age of a year, which had been produced by the Bataillon method of pricking the unfertilized egg. Thus the ovum can be activated by purely physicochemical means, although the result is an organism whose somatic cells lack one half the normal number of chromosomes.

Another line of investigation to which he gave many years was that of the composition of colloids which led to the development of his new theory contradicting the prevailing one that the proteins of living bodies were colloids. In 1917 he read a paper in which he denied the theory that war was necessary in order to preserve the virile virtues. He said: "If we succeed in substituting for the present one a new type of statesmen, who are familiar with and follow the development of the exact sciences, and who are willing and capable of applying the result of exact science to the intellectual, moral, physical and economical uplift of the masses, we shall at least diminish the danger of war."

Loeb was a prolific writer on his specialties and many of his works are still standards. He had honorary degrees from Cambridge, England, and from Geneva and Leipzig, and was a member of many prominent scientific bodies, both in this country and abroad.

HARRY S. FINCKE, M.D.,

Astoria, N. Y.

Dr. Harry S. Fincke died at his home in Astoria on January 21st after a long period of ill health, due probably to his prolonged service in the World War. He had recently returned from a sojourn in Florida, where he went in a vain effort to regain his health. His son furnished some of his blood in an endeavor to save his father's life through transfusion, but even this was to no purpose.

Dr. Fincke was born in Scotland fifty-five years ago. He was graduated from the Cornell Medical College in 1903. He was a member of the Queens-Nassau Medical Society, of the Long Island City Medical Society, of the Medical Association of Greater New York, and of the Associated Physisians of Long Island. During the World War, he was a major in the U. S. Medical Corps, and since his return had been active in rendering medical aid to soldiers and sailors through the Red Cross.

News Items.

Grip Epidemic in Mexico City.—A serious epidemic of grip has spread in Mexico City. More than 5,000 cases have been reported to the medical authorities, according to cable reports.

New Hospital Project.—The Physicians' Medical Hotel Company has purchased the fourteen story building at Fifty-seventh Street near Columbus Avenue, known as the Emerson Hotel, to be remodeled into a hospital.

Riverside Hospital Clinics.—A clinic in contagious diseases for physicians will be given the last Tuesday of each month at 3.30 p. m. by Dr. Charles Hermann and Dr. E. L. Benjamin. Boat leaves foot of East 134th Street, Bronx, at 3 p. m.

Workers' Psychiatric Clinic.—The United Workers of Norwich, Conn., in conjunction with the State Board of Health and the Norwich State Hospital, have opened a neuropsychiatric clinic. Miss Betsy Mitchell is organizing the social work.

Dr. Eichel Sails for Geneva.—Dr. Otto R. Eichel, director of vital statistics of the New York State Department of Health, sailed for Geneva on February 20th, to direct the epidemiological intelligence and statistics section conference of the League of Nations.

Dr. Alice Hamilton Appointed to Health Organization of League of Nations.—Dr. Alice Hamilton of the Harvard Medical School has been appointed a member of the permanent health organization of the League of Nations, which convened in Geneva during the week of February 13th.

Neurological Institute Maintenance Plans.—Announcement has been made of the organization of the cooperative committee of the Neurological Institute of New York by Miss Mabel Choate, vice-president of the board of trustees. The object is to promote the interests of the hospital and to raise funds for its maintenance.

Dr. Thomas B. Lee Addresses Health Officials.—Marriage of persons below average mentality was attacked by Dr. Thomas B. Lee of Camden, President of the State Board of Health, at the fourteenth annual meeting of the State and local health officials. He also advocated sterilization of criminals and imbeciles and birth control.

Dr. Abbott Demonstrates New Instrument.—An instrument by which heart beats may be heard at a distance has been perfected by Professor R. B. Abbott of Purdue University, who, according to newspaper reports demonstrated the device before a clinic of physicians attending the American Congress of Internal Medicine, in their session at St. Louis.

Rochester University Medical School Nearing Completion.—The University of Rochester Medical School will be formally opened in September, 1925, according to its present plans. The medical school and buildings are in process of completion and will be augmented by the Strong Memorial Hospital and a municipal hospital to be built by the City of Rochester.

Rockefeller Endows Oxford Chair of Biochemistry.—The trustees of the Rockefeller Foundation have offered £75,000, normally about $365,000, to Oxford University for the endowment and development of the department of biochemistry. The trustees decided to make their offer at a meeting December 5th, conditional on the university raising an unstated amount of money.

Status of Sheppard-Towner Act. — The Sheppard-Towner Maternity and Infancy Act has been accepted by twenty-nine States during 1923, increasing by forty the total number of States cooperating, under legislative sanction, with the Federal Government in activities for the reduction of maternal and infant mortality. The only States in which the act is not now operative are Connecticut, Illinois, Kansas, Louisiana, Massachusetts, Maine, Rhode Island, and Vermont.

Tuberculosis and Industrial Hygiene Course.—A six weeks' combined course on tuberculosis and industrial hygiene for medical practitioners has been arranged at the Academy of Medicine under the joint auspices of the Public Health Committee of the Academy, the New York Tuberculosis Association, and the Division of Industrial Hygiene of the New York State Department of Labor. The lectures will be held at the Academy of Medicine on Tuesday and Friday afternoons at 4:30, beginning March 14th and ending April 22, 1924.

Doctors Sail for Europe.—Sailing recently from New York to the Mediterranean, on the White Star Liner *Adriatic* are Dr. Charles L. Dana, Dr. M. Allen Starr, and Dr. Joseph Collins.

St. Luke's Hospital Elections.—At a recent meeting of the medical board of St. Luke's Hospital the following officers were elected for the year 1924: President, Dr. Henry S. Patterson; vice-president, Dr. Francis C. Wood; secretary, Dr. Winfield S. Schley.

$200,000 Bequest for Study of Children's Diseases.—Dr. Livingston Farrand, president of Cornell University, has announced a legacy of $200,000, from an anonymous donor, for the establishment of an endowment fund for research work in its department of pediatrics.

New York Has Lowest Death Rate.—The death rate in New York City last year was the lowest in the history of the city, being 11.72 to the thousand inhabitants. This is a reduction of 8.54 since 1898, when the present City of New York was consolidated. This means a saving of 120,093 lives and gives New York City the lowest death rate of any large city in the world.

To Discuss Psychoanalysis.—An open meeting of the New York League for Mental Hygiene of Children was held on February 28th at the Art Centre, 65 East Forty-sixth Street, at 8 o'clock. Dr. Joseph Ash and Dr. Elizabeth Severn spoke on Psychoanalysis and Prevention, and Dr. Eleanor Crosby Kemp on The Need of Art as Selfexpression.

Beth David Hospital to Further Its Work.—The annual dinner of the trustees of the Beth David Hospital, held on February 18th, at the Hotel Commodore, was marked by contributions of $40,000 to further its work. Among the speakers were James A. Hamilton, New York's Secretary of State, and Dr. John J. McGrath, president of the medical board of Bellevue and Allied Hospitals.

High Rents Cut Birth Rate.—High rents are partly responsible for a decreasing birth rate in Chicago, according to a report of State Health Commissioner Isaac D. Rawlings. The report shows 19.4 births for each thousand of population, as against 20.6 births for last year, and 11.7 deaths against 11.3 for 1922. The rest of the State has a birth rate of 19.5 and a death rate of 12.3 per thousand.

Dr. Loeb Eulogized.—Dr. Simon Flexner, head of the Rockefeller Institute, Dr. William H. Welch, president of the Johns Hopkins Medical School, and Dr. W. J. Osterhout, professor of physiology at Harvard, were the speakers at the memorial meeting, held at the Rockefeller Institute, in tribute to Dr. Jacques Loeb. Many friends and associates were present to hear the eulogies paid the great research worker.

New York Academy of Medicine Sites.—The trustees of the New York Academy of Medicine have received several advantageous offers for the new site at Park Avenue and Sixtieth Street. One of these proposes to give in exchange a site seventy-five feet front on Fifty-seventh Street, one hundred feet on Fifty-sixth Street between Eighth and Ninth Avenues, containing 5,500 square feet more than the Park Avenue site, and the sum of $500,000 in addition.

Neurology and Psychiatry Courses at Columbia.—Columbia University announces a series of courses in neurology and psychiatry for qualified graduates in medicine, as a part of its university extension and school of medicine. These sessions, lasting either eight or twelve weeks, will utilize the clinical material at the neurological department of Vanderbilt Clinic, the New York Neurological Institute, the Central and Neurological Hospital, and the Manhattan State Hospital for mental diseases.

Open Meeting on Proposed Medical Legislation.—At an open meeting held by the committee on civic policy of the Medical Society of the County of New York at the Academy of Medicine, the new medical practice act, proposed at Albany, which includes annual reregistration of physicians, was discussed. The narcotic bill, proposed by the Bar Association, was taken up. County Society members, as well as representatives of the health department, bar association, and the narcotic division of the police department were present. The point was taken up to limit the enforcement of the reregistration measure to a period of five successive years in order to organize the machinery to clean the State of quackery. After that time the physician need not reregister. However, it was stressed that no power to revoke a physician's license for failure to register is granted to the regents or anybody else by the proposed act.

BALBOA HEIGHTS, C. Z., *January 21, 1924.*

HEAD TROPHIES

Panama, as the crossroads of the world, contains many medical curiosities from other countries. One of the most interesting of these are the shrunken heads of human beings and animals which come from Ecuador and are not infrequently offered for sale, particularly at those seasons when there is a large influx of tourists whose one desire seems to be that of donning Panama hats (which by the way are not made here but at Monte Christe and Jipijapa in Ecuador) and purchasing anything which is shown them. Not infrequently a very good head may be secured for fifty dollars gold, but of course the rule is to charge all that the traffic will bear. Several times cat or dog heads have been offered for sale and on one occasion the entire body of a negro, shrunk to a twenty-eight inch stature, was exhibited in a local barber shop. Human heads about two inches in diameter and complete in every particular are seen more frequently than any type of this "art." These are usually the heads of males, sometimes of negroes, sometimes of Indians, although once in a while a woman's head with long hair is shown. They are generally slate grey in color, the hair, beard and eyebrows being well preserved and the diminutive features being uncannily lifelike in their expression. It is always interesting to speculate just how the bones have been removed and the soft parts preserved and shrunken and always it is alleged that there is a great mystery about the process since the wild Indians of the Jibaro country are not at all hospitable to strangers and consider the process of head shrinking a sacred ceremony not to be disclosed to outsiders. It is stated that several persons who have allowed their curiosity about the matter to outrun their prudence have supplied fresh material for these primitive morticians. Several years ago a considerable number of photographic plates of the process which had been secured by an enthusiastic young Frenchman were shipped to France from here as a part of his estate.

While none of the medical men on the Isthmus knows for a certainty the entire process of reducing a head from normal proportions to those of a doll, enough data have been secured from passing travelers to constitute a fairly accurate knowledge. The head is severed as close to the trunk as possible and an incision made from the occipital protuberance downwards. The skin and soft parts are then reflected and all fat and tissue not necessary to preserve the features removed. The shell remaining is turned right side out after sewing up the incision at the back of the neck and the lips. Hot stones are then introduced and by a rotary motion a charring, shrinking and thinning of the tissues is produced. The head is then boiled in a strongly astringent solution, probably of high tannic and benzoic acid content. It is then packed full of very fine sand and strapped to a board which has a small hole drilled through it. The centre of the neck is directly over this hole and as the head, which is set out in the broiling hot sun, shrinks, the sand slowly is forced through the opening. While this is going on the features are deftly moulded, particular attention being paid to the preservation of the hair of the head, the brows and face. When the process is completed the head is filled with a reddish pitch which hardens and is only visible at the base of the severed neck.

It is remarkable that these heads are not at all revolting in appearance. On the contrary, the features are so skillfully moulded that there is something pleasing about the individuality of countenance which these heads possess.

MEDICAL ASSOCIATION OF ISTHMIAN CANAL ZONE

The 205th meeting of the Medical Association of the Isthmian Canal Zone was held at the Century Club in Panama January 21, 1924, as the guests of the Herrick Clinic. Dr. John J. Moore, the former secretary-treasurer of the association, was installed as president, Dr. K. P. Taylor, as vice-president, and Dr. C. R. Mueller, as secretary-treasurer. An interesting program was presented and after the completion of the discussions the association refreshed itself in a manner which would excite the bitter envy of similar organizations in the United States.

TEACHING HYGIENE IN CANAL ZONE SCHOOLS

Miss Jean and Miss Abbott, of the American Child Health Association, are at present on the Isthmus making a study of the teaching of hygiene in the public schools with a view to its extension and to a readjustment of the emphasis of the instruction in order that it may be better fitted to tropical life. While their report has not yet been made, the problem seems to be largely one of administrative rearrangement, since many of the difficulties usually met in the temperate zone do not exist here. Housing is well nigh perfect in the Canal Zone; it is not necessary to teach the basic lesson of the open window and ventilation in a climate where air in motion is essential to comfort. Bathing is another thing that our children do not have to be taught because frequent baths are necessary if one is to be allowed to associate with others. Daily exercise is the rule among Zone children. There exists, however, great need for teaching oral hygiene; the value of the well balanced ration is not well enough understood; and the inculcation of those personal habits which will prevent the spread of the sputum borne infections is continuously necessary. In addition to their work in American territory, Misses Jean and Abbott will inspect some of the schools of Panama, especially with the aim of cooperating with the Ministry of Public Education for the expanded teaching of public health pedagogical methods in the National Normal School. If their time will permit they also contemplate a visit to San Jose for a similar purpose. The Canal Zone Government through whose invitation these ladies are carrying on their work is cooperating heartily with them through the Health Department and the Division of Schools.

MARITIME QUARANTINE CONFERENCE

Official announcement of the Conference of Maritime Quarantine Authorities of the West Coast of South America for the purpose of standardizing and rationalizing quarantine methods in that litoral has

been made by the Panaman Government. The conference will convene on the morning of February 25th and will continue until February 29th. Invitations have been accepted by the Governments of Ecuador, Peru and Chile. The delegation from Panama is headed by Dr. Augusto S. Boyd, president of the National Board of Health. Panama's other delegate is Surgeon William Colby Rucker, United States Public Health Service, who is the secretary-general of the conference. Ecuador is sending Dr. Wenceslao Pareja, national director of health, and one other delegate to be announced later. From Peru will come Dr. Sebastian Lorente, national director of health, and Dr. Paz Soldan, professor of hygiene in the university, and from Chile, Dr. R. Corbalan Melgarejo and a delegate who has not yet been announced. The steamship lines running between Panama and the ports of Ecuador, Peru and Chile have granted favorable rates to the delegates and the members of their official parties and a considerable attendance from those countries is anticipated. From the United States, it is expected that Surgeon General Hugh S. Cumming and Surgeon S. B. Grubbs, quarantine officer of the Port of New York, will come as representatives of the United States Public Health Service, while Assistant Surgeon General John D. Long, United States Public Health Service, will attend for the Sanitary Office of the Pan-American Union. Colonel H. C. Fisher, Medical Corps United States Army, Chief Health Officer, will represent the Panama Canal. A representative of the British Ministry of Health is scheduled to be present and observers from France and other European countries will probably participate in the conference. The Rotary Club of Panama at its meeting of January 17th appointed a committee, of which Dr. D. F. Reeder, of the Herrick Clinic, is chairman, to cooperate with the secretary-general of the conference. The club will give a luncheon to the delegates. The Isthmian Canal Medical Association will hold a special meeting for the conference at Santo Tomas Hospital on February 28th. The session will be in Spanish and the program, which is being arranged by Dr. A. S. Boyd, chief surgeon of the Santo Tomas Hospital, will be presented by Panaman physicians. The society will also give a formal banquet to the conference.

LONDON LETTER

(*From our own correspondent*)

LONDON, *January 18, 1924.*

THE TEACHING OF MOTHERCRAFT

A congress on education was held recently in London at which some instructive topics were discussed and analyzed from the medical and psychomedical viewpoints. One subject discussed was the teaching of mothercraft to schoolgirls. Dr. Janet Campbell, medical officer to the Ministry of Health and chief woman medical adviser to the Board of Education, who presided, said they had to consider when was the best time for education in mothercraft to be imparted. Should they wait until the baby was born and the mother was attending an infant welfare centre, or was being visited in her own home by a health visitor, or should they try to reach her after marriage and before her baby was born? Or should they go one step farther back and attempt to teach the adolescent girl, at a secondary school, a continuation school, an evening institute, at a club or some such place? Or should they begin right away at the beginning and teach the older girls at the public elementary school, which was, after all, the only time and place that they could be sure of getting the girls who were to be the future mothers and make a beginning with them. Dr. Campbell advocated a limited method of teaching the science and duties of mothercraft, and said that the Board of Education had adopted the view that such teaching should begin with the older girls in the elementary schools. Miss Morson, superintendent of the Malvern Child Welfare Centre, said that girls should begin to learn the fundamentals of mothercraft at thirteen or fourteen years of age. It seemed to her that girls in the higher classes in the secondary schools, the boarding schools, the finishing schools, and in the Women's University should all be taught the elements of mothercraft. The teaching, she said, appealed to girls very strongly, and one had no difficulty in arousing their interest. The teaching of mothercraft would prove a great asset to the country in the future and Government grants should be made available for the purpose.

THE OLDER CHILDREN IN ELEMENTARY SCHOOLS

Sir Henry Hadow, president of the congress, was in the chair when the subject of the older children in the elementary schools was considered. Dr. P. B. Ballard, inspector, London County Council Education Committee, declared that England had two separate systems of education very badly coordinated, the elementary and the secondary. In London the brightest boys in the elementary schools passed on to the secondary schools, the next brightest to the central schools, excellent schools which were secondary schools in everything but name; but still there were about ninety per cent. of the children who remained in the elementary schools and left at the age of fourteen. This scheme was by no means satisfactory. It was satisfactory for ten per cent. of the children and very unsatisfactory for ninety per cent. How were they to do justice to the ninety per cent. who remained in the ordinary elementary school? It was true that, in London at least, these children were able to attend handicraft and domestic economy centres, a few schools having also special science and art rooms. But the bulk of the schools in England and Wales were not much better off now than they were forty years ago. The children were not taught a foreign language; they were not taught practical science, and they did not remain in school beyond the age of fourteen. The schemes of reform before the country had certain elements in common. They all agreed in regarding as an anomaly the existence of one system of education for the poor and another for the rich. They held that the distinction between secondary and elementary schools should be abolished; that there should be but one current of education, not two, and that the only distinction should be between the two stages of one process, that all children up to the age of eleven should be regarded as in the primary school, and beyond the age of eleven as being in the secondary school. To regard education from that point of view

they must alter their notions as to secondary education. This should not mean a grammar school education, but the education of the adolescent. The feature of the reform schemes was a definite clean cut at eleven years of age, the beginning of an important psychological period, the beginning of adolescence.

THE SOCALLED BAD BOY

The bad lad was the subject dealt with by Mr. Alexander Paterson, one of His Majesty's Commissioners of Prisons, before a session of the Training College Association. "How many bad lads are there?" asked Mr. Paterson. Every year seven thousand boys were brought up at police courts in England and put on probation; fifteen hundred boys were sent to industrial and reformatory schools, and another five hundred boys were sent to Borstal institutions. Another thousand went to prison who had never previously been in trouble at all. "I will make this rough guess," added Mr. Paterson, "that of every hundred boys leaving elementary schools one is a bad boy in the sense that sooner or later he comes into conflict with the law." Speaking from his experience among all the many bad boys he had known, Mr. Paterson said he had come to the conclusion that there were necessarily three elements in the commission of a crime. There was first the desire to do something wrong, a desire which everyone had at one time or another; secondly, the opportunity to satisfy the desire; and, thirdly, the absence or extreme weakness of any inhibition to the contrary. It was in respect to that last mentioned very necessary ingredient to the commission of a crime that one boy was different from the other ninety-nine boys in a hundred. The ninety-nine had been supplied by home or school training with an inhibition which the hundredth boy lacked. What psychologists called an inhibition theologians called conscience, but the inhibition often arose from the nature of one's social environment. The lad going to a high class school learned a thousand and one inhibitions, things one must not do or say.

A secondary school boy would learn five hundred inhibitions, while in the elementary schools there were fewer inhibitions. The first thing to do with the bad lad was to study his desires, and the second, to encourage the ordinary growth of inhibitions. How were these things being done? In this country we did not agree with the old methods of death or detention in the treatment of the bad lad who came within the clutches of the law. Therefore, throughout our system, a number of new methods were being tried in order to find out the right way of dealing with the bad lad. It was a remarkable fact that more of the bad lads were being dealt with out of the institutions than inside. Paying tribute to the Borstal institutions, he said that their houses protected the growth of inhibitions. Of every ten Borstal boys seven never got into trouble again. But they still had bad boys under twenty-one entering prison. Those responsible for His Majesty's prisons would like to shut the gate in front of every lad under twenty-one, but they were the servants of the courts and they had to open the gates. The Prison Commissioners, however, were doing their best. He believed that in time, if only they had special places to which bad lads might be remanded —not prison—it might be possible to determine more scientifically what really was wrong with the lad and what sort of treatment or training should be prescribed for him. There were three very clear ways in which the teaching profession of the country could help the bad lad. When he was at school he was often the least attractive fellow in the class, and that was the kind of lad upon whom the teacher should concentrate more than upon all the others. In regard to the boy's afterschool life, there was a natural temptation to every teacher to keep mostly in touch with his best boys. But it should be the duty of the teacher to keep particularly in touch with the bad lad, to make sure that he got a job and to look after the way in which he spent his evenings. He had been wondering whether it was not possible for the teaching profession to play a great part in the administration of the Probation of Offenders' Act. His third suggestion was that teachers should be honorary probation officers, to whom the regular probation officers should pass cases.

RADIUM AND DISEASE

Professor Sidney L. Russ lectured recently at King's College, London, on radium and x rays. Since the discovery of radium twenty-five years ago a vast amount of knowledge, he said, had been gained about the physical properties of radioactive substances, and perhaps the next quarter of a century would reveal with equal clearness the action which radium rays and x rays had upon living structures. These agents were very largely used in the treatment of disease, particularly in cancer, and there was little reason to doubt that they were important aids to the physician and surgeon, but at the same time exaggerated hopes in their efficacy were to be deprecated. The action of these rays on the tissues of the body were extremely complex, and, although a great deal of research work, experimental and clinical, had been done, their fundamental nature had not yet been established. In view of such complexity it was not to be wondered that finality had not been reached.

HOSPITAL SERVICE AT THREE PENCE A WEEK

At Brighton in Sussex a few years ago was initiated a scheme whereby workers who contributed three pence a week were assured of hospital accommodation and service for themselves and dependents without further charge. The scheme appealed to the governors of certain London hospitals, for while it made sure of a regular revenue, it did not place a heavy burden on anyone. It was thought that the scheme, though successful in the country, might not be workable in London, and two trial associations were therefore formed, one for "black coated workers," known as the British Provident Association for Hospitals and Additional Services, to which the annual subscription varies from £1 1s to £2 2s a year, and the other the Hospital Saving Association, for persons earning from £4 to £6 a week, the subscription being threepence a week or twelve shillings a year. Each organization obtained thousands of members, and now at the end of the trial year the accounts have been examined by experts, with the result that the scheme is declared sound and practicable. As all members pay through the association any suggestion of charity is removed.

Book Reviews

LABORATORY METHODS OF BLOOD ANALYSIS

Blood Chemistry Colorimetric Methods. By Willard J. Stone. New York: Paul B. Hoeber, Inc., 1923.

This book contains in a convenient form a compilation of the methods used in a chemical laboratory for blood analysis. Its chief point of variation from other outlines of laboratory procedures is the inclusion of a page or two of clinical comments at the end of each chapter. One chapter deals with the dietary control of disturbances of metabolism, and contains a list of neutral, alkali, and acid producing foods. The final chapter describes the test and maintenance diets of Joslin in the treatment of diabetes mellitus. The book is a useful one for both the laboratory technician and the clinician.

DIETETICS

The New Dietetics. By John Harvey Kellogg, M.D., LL.D., F.A.C.S. Battle Creek, Michigan: Modern Medicine Publishing Co., 1923.

This is a book of more than one thousand pages containing much that is found in the usual textbook on dietetics, as well as much not usually found therein. It is not necessary to mention the usual, therefore attention will be drawn to some of the unusual features which have impressed the reviewer. The pages relating to the food salts and minerals are valuable. Two tables are especially noteworthy. One gives the lime content of many of our most commonly used foodstuffs, including grains of lime to the ounce, weight of one hundred calories, weight of the usual amount of raw food for an ordinary serving and calories in an ordinary serving. The other gives the same data for iron. The table on vitamines is also a very good one.

Much useful information is given regarding various articles of food in that part of the book where each article is taken up separately and discussed. This discussion is, by the way, written in an interesting manner. There are in all forty-four tables contained in this book. More than thirty of these concern the composition of foods. The ones which I have mentioned regarding lime and iron give a fairly good representation of the value of these tables.

PHARMACOLOGY

Der Einfluss experimentell-pharmakologischer Forschung auf die Erkennung and Verhütung pharmakotherapeutischer Irrtümer. Von Professor Dr. Emil Starkenstein in Prag. Immunodiagnostik und Immunotherapie. Von Professor Dr. H. Selter, Direktor des Hygienischen Instituts der Universität in Königsberg i. Pr. Leipzig: Verlag von Georg Thieme, 1923.

These two monographs constitute the first volume of a series called the *Irrtümer der allgemeinen Diagnostik und Therapie sowie deren Verhütung,* written under collaboration by several authors and edited by Prof. Dr. J. Schwalbe of Berlin. The first monograph deals with the influence of experimental pharmacological studies upon the recognition and avoidance of pharmacotherapeutic errors. Pharmacological studies are not always directed toward the practical application of the subject investigated and it is a well known fact that clinicians and those engaged in the theoretical side of medicine have very often and for a long time worked side by side without cooperation and even without recognition of the importance of each others work. Consequently pharmacotherapeutic practices have persisted as a result of conservatism even though the results of experimental pharmacological investigation had rendered them obsolete. The author endeavors to initiate a more rational therapy by showing the relationship of pharmacology to drug therapy and the mistakes commonly made as well as how to avoid them. Symptom complexes are divided into two groups: 1, those which do not appear as the result of disease entities, and 2, independent symptom complexes which are produced by changes of definite organic functions. The conception of this work and its execution is original.

Immunodiagnosis and immunotherapy depend upon the phenomena occurring in the bodies of infected persons or animals and are applicable to the diagnosis and therapy of infections. The difficulties in this branch of medicine are much greater than in chemical investigations or drug therapy, in which there is at least one known substance the action of which is not based entirely upon theory. Immunodiagnosis is made even more difficult because the investigations are usually not made by the clinician or general practitioner but by the laboratory. Both immunodiagnosis and immunotherapy are based upon Ehrlich's theory of antigen and antibody. The subject of immunodiagnosis includes the elements of agglutination, precipitation, bacteriolysis and complement fixation, the use of protective ferments and the Abderhalden reaction, and the use of bacterial toxins. Immunotherapy includes serotherapy, vaccinotherapy, bacteriotherapy, specific and nonspecific stimulating therapy and proteotherapy. The use of these various agents in infectious diseases is discussed in detail.

THE DAILY WALK

Walking for Health. By Alvah H. Doty, M.D. New York and London: D. Appleton & Co., 1923.

This practical little guide of less than fifty pages is very timely for perhaps at least two reasons. First, it should help to counteract the sedentary habits brought about by the present day necessity that so many have to meet of traveling long distances to and from daily work in some form of conveyance, be it automobile or subway; for, much as there is to say in favor of straphanging as a difficult physical feat, it surely cannot be classed as a beneficial form of exercise. Second, this little book should make a very definite appeal to the many—and their number seems to be constantly increasing—who find much joy in hiking, climbing and the like, either alone or in groups. They will find their pleasure in walking justified, not only for its own sake, but because systematic daily exercise in the open air lays the foundation for much of the body's health and strength.

Some of the advantages to be derived from the

daily walk are that it can supply the most effective and natural means of protection against the congestion of internal organs when this is not caused by disease; it exercises not only the great muscles of the legs, but the rest of the external muscles of the body, and in this way increases the capacity of the chest and provides, according to Doctor Doty, all necessary exercise except that called for in the instance of special athletic work.

"The following pages contain truths of great importance in the preservation of health and the prolongation of life," writes Dr. George David Stewart in his introduction to the volume. "These truths are not new; they have been known for a long time; in fact, so well known that they have become familiar and that familiarity has bred contempt. However, the attractive, concise manner in which they have been restated by Doctor Doty will, I hope, impress their value upon every one into whose hands this little volume falls."

CONTAGIOUS DISEASES

Infektionskrankheiten. Von Geh. Med. Rat Prof. Dr. M. Matthes. Mit 1 Abbildung, 19 Kurven und 1 farbigen Tafel. Zweite, verbesserte und vermehrte Auflage. Leipzig: Verlag von Georg Thieme, 1923. Pp. 156.

This is a revised edition of No. 9 of the series of *Diagnostische und therapeutische Irrtümer und deren Verhütung, Innere Medizin.* It deals with the subject of acute contagious diseases. Inasmuch as the diagnosis in these diseases depends to a great extent upon the laboratory, there must be cooperation between the diagnostician and the laboratory worker. However, as the laboratory is neither infallible nor the only method of arriving at a diagnosis, it should be supplemented by clinical study. A negative bacteriological and serological finding must be carefully and circumspectly interpreted; even a positive finding may be erroneous. The examination of the blood and urine should not be neglected as they frequently reveal valuable information. The value of the blood examination is particularly stressed. The diseases in which diagnostic and therapeutic mistakes are likely to be made are discussed.

ELECTROTHERAPY

The Note Book of an Electrotherapist. By Mel. R. Waggoner, M.D. Chicago, Ill.: McIntosh Electrical Corporation, 1924.

There is widespread interest among physicians today in the newer methods of electrotherapy which were extensively applied in the war hospitals and which are being put more and more into clinical use. There is a distinct need for the adequate teaching of electrotherapeutics in our medical schools and postgraduate institutions and also a distinct need of clearly written textbooks free from individual overenthusiasm or commercial influence, giving the proved essentials of electrotherapy and physiotherapy.

Dr. Mel. R. Waggoner, who has been giving lectures on electrotherapy in the employment of a manufacturer of electrical apparatus, has written a booklet of 173 pages pertaining to the practical applications of electrotherapeutics. In his much too short description of the fundamentals of electricity, he fails even to mention static electricity with its limited but important uses. He also fails to say anything about the rationale and application of radiant light and heat, considered an indispensible introduction to almost any form of electrical application with the exception of diathermy. He describes only the apparatus manufactured by his employers. Under therapeutics, he gives a detailed description of his technic in eye, ear, nose and throat cases, while the treatment of chest conditions is dealt with under the chapter on electrodiagnosis. A separate chapter deals with the description of the application of his pelvic multimode, which is some sort of a shotgun apparatus through which all conceivable pathological conditions in the pelvis can be aimed at.

Dr. Waggoner's *Note Book* has its useful purpose in serving the students of his course and the buyers of one make of electrical apparatus. It is to be hoped that the concerted efforts of those practising electrotherapy in a serious way will soon be able to give the medical profession courses of instruction and textbooks on the same plan as the other recognized specialties of medicine.

RACE DECADENCE

Race Decadence: An Examination of the Causes of Racial Degeneracy in the United States. By William S. Sadler, M.D., F.A.C.S. Illustrated. Chicago: A. C. McClurg & Co., 1922.

Notwithstanding the suspicion that the author entertains pessimistic views as to the future of the American people, if we can judge correctly by the subtitle of this work, we are assured by the author himself that he is not a pessimist, and that even though this volume may not offer the most pleasant reading from the viewpoint of the future, there is still balm in Gilead. He also assures us that the present volume is to be followed by others which will deal with race betterment, and will present "the encouraging and more optimistic side of this momentous question." For this let us be thankful. We are hearing so much these days of the menace to white supremacy of a certain religious type and brand, that our optimism as to the actual superiority of the white brand of humanity is being seriously shaken by the thought of what those terrible colored and semitic minorities have in store for their superior white majorities, not only in the United States but in other countries as well.

The present volume deals with race decadence under two heads, physical decadence and mental degeneracy. Whichever way we turn, the race in America is surely in a bad way, and the future looks dark indeed. Considering the increase in nervous and mental diseases, and the prevalence of physical disease, much of which is on the increase, there can be no doubt that the integrity and stability of the American people are threatened, according to the author. And his data undoubtedly confirm his worst fears.

Fortunately again, the author declares that he is not immediately alarmed over the threat of the conditions which confront us, and which he has endeavored to portray in his book. He still has great faith in the future greatness, attainment and development of the American people, but he feels it his duty to point out the evil influences which are

at work tending to jeopardize the white races in general and the American stock in particular. The volume is filled with data collected from innumerable sources, it is well written and arranged, and altogether makes interesting though not very encouraging reading. Let us hope that the promised optimistic volumes will appear shortly and that they will show us something of the sunny side of our national future.

SURGERY OF LOWER EXTREMITIES

Verletzungen und chirurgische Krankheiten der unteren Extremität. Von Professor Dr. Erich Sonntag, Vorstand des Chirurgichpoliklinischen Instituts der Universität in Leipzig. Mit 25 Textabbildungen. Leipzig: Verlag von Georg Thieme, 1923.

This monograph constitutes the eleventh number of the surgical section of *Diagnostische und therapeutische Irrtümer und deren Verhütung,* written under the collaboration of several authors and the editorship of Schwalbe. The various injuries and surgical diseases of the lower extremity are discussed in detail with emphasis upon the important points which enable one to avoid diagnostic and therapeutic mistakes. The subject matter is treated topographically, rendering reference to the various diseases affecting the different regions easy.

INTERNATIONAL CLINICS

International Clinics: A Quarterly of Illustrated Clinical Lectures and Especially Prepared Original Articles by Leading Members of the Medical Profession Throughout the World. Edited by Henry W. Cattell, A.M., M.D., Philadelphia, Charles H. Mayo, M.D., and others. Philadelphia and London: J. B. Lippincott Company, 1923.

Twenty-eight authors contribute to this interesting volume. The subjects considered include instructive articles on the Therapy of Allergic Diseases (Van Leeuwen), The prevention of Falling Hair (Van-Harlingen), Cancer Considered as a Constitutional Disease (Bulkley), Psychology of the Unconscious (Bowers), Thyroid Therapeutics (Berkeley), and others equally interesting and instructive. The volume is in all respects the equal of its many excellent predecessors in this series and constitutes a valuable addition to the physician's library.

POISON IVY

Rhus Dermatitis. From Rhus Toxicodendron, Radicans and Diversiloba (Poison Ivy). By James B. McNair. Chicago: The University of Chicago Press. 1923.

This book of 298 pages represents an enormous amount of work conscientiously done; and, so far as the reviewer knows, is the first complete work dealing with poison ivy. Many physicians who are interested in the subject have undoubtedly encountered McNair's articles in various journals devoted to medicine, botany, chemistry and so forth; some of these isolated publications are incorporated in this volume. With possibly a single exception, every conceivable phase of the subject of ivy poisoning is taken up in great detail. The work is divided into sixteen chapters, together with an appendix, a long bibliography and a nearly complete index. There are fifteen illustrations and three plates, showing tracings of leaves of rhus plants, cross sections of various plant preparations, microphotographs of sections of affected skin, and so forth. It is to be regretted that the author omitted a series of photographs depicting the different poisonous plants as they are encountered in their natural state.

Beginning with the history and distribution of the poison ivy plants, the author takes up their morphology and anatomy, both gross and microscopic; the origin and occurrence of the poison; its chemistry; the transmission of the poison from plant to person; the pathology of rhus dermatitis; internal poisoning from rhus; immunity; remedies. The last chapter is entitled A Contribution to the Chemotherapy of Rhus Dermatitis and Tentative Method for Treatment. Each chapter has a complete summary, adding greatly to the value of the text.

The book is incomplete, however, with respect to treatment of ivy poisoning. The work of Dr. A. Strickler, of Philadelphia, who has written several articles on the subject of treatment by means of injection of alcoholic extracts of rhus toxicodendron, is not even mentioned by McNair. In the reviewer's opinion, this is a grave and unfortunate omission. Strickler's treatment has produced excellent results in the hands of several practitioners of good repute. It is to be hoped that a new edition of the book will include this important phase of treatment.

HEALTHY MOTHERS AND CHILDREN

Healthy Mothers. By S. Josephine Baker, M.D., D.P.H. Boston: Little, Brown & Co., 1923.

Healthy Children. By S. Josephine Baker, M.D., D.P.H. Boston: Little, Brown & Co., 1923.

Two acceptable little volumes, one devoted to the health of the expectant mother and the other to the health of the growing child. Innumerable books on these two subjects have been written. These little volumes contain no more than has already been written and reiterated. But they are well got up, easy to handle and comprehensively and cheerfully written. They can therefore be recommended without qualification to the woman who wishes to have the best practical information on the subject and uptodate methods in the nursery.

THERAPY

Medikamentenlehre für Krankenpfleger und Krankenschwestern. Dr. Paul Fleissig. Mit einem Vorwort von Professor Dr. R. Staehelin. Fünfte, vermehrte und verbesserte auflage. Berlin, Wien: Urban & Schwarzenberg, 1923.

This is the fifth edition of a handbook on the use of drugs and other remedies, intended for use by nurses. In a brief and interesting manner the author describes the properties and manner of preparation of the most important therapeutic agents. Some practical points in the handling of the necessary apparatus are given. There is also a short discussion of the subject of disinfection. It is important that the nurse should know something about the care, keeping qualities and the signs of deterioration of the therapeutic agents in common use. All knowledge is power and must consequently increase the efficiency of the nurse. This book is a valuable adjunct to the usual textbook on materia medica for nurses, as it contains much material that is not usually found in such books, especially those printed in the English language. The English writers may well profit by this example. The physician will also find some valuable hints in this book. The drugs are

studied from the viewpoint of their origin, preparation and properties, as well as their therapeutic effects. The remainder of the book deals with the undesirable byeffects of drugs, practical nursing hints and miscellaneous matter which every practical nurse should know.

DIABETES

Uber Eiweissbeschränkung des Diabetes gravis. Von Prof. Karl Petrén. Unter redaktioneller Mitworkung von Dr. S. Lang, Karlsbad. Halle a s.: Carl Marhold Verlagsbuchhandlung, 1923.

This monograph constitutes Band viii, Heft 5 of the series of *Verdauungs- und Stoffwechsel-Krankheiten,* edited by H. Strauss. Inasmuch as the starvation method of treating diabetes has not proved entirely satisfactory, the author has endeavored to develop the method of restricting albumin in the severe cases of diabetes, thereby avoiding the dangers of undernutrition and acidosis. The case histories cited accurately indicate the quantity of food ingested, the daily determination of the blood sugar content and of the excretion of nitrogen, the urinary sugar and of the acetone bodies. The dietetic measures used are described in detail and the results obtained are presented in tabular form. The subjects of blood sugar, carbohydrate tolerance, body weight and the general condition of the body and acidosis are discussed in the light of the results obtained. The subjects of nitrogenous metabolism in diabetes, the pathogenesis of acidosis and the sensitiveness of the organism to nitrogen in severe diabetes are discussed from the theoretical standpoint.

Medicoliterary Notes.

When diploma mill doctors deal death, the public is horrified. When genuine doctors ask for laws to protect the people from quacks and charlatans, a large and vocal part of the public sides with the get-degrees-quick imposters and takes up their cry of bigotry, monopoly, and persecution. This is the history of medical legislation everywhere. And, since legislators hear the voice of the people much more clearly than the voice of the expert, the diploma mill doctor who lacks knowledge, training, and professional honor continues to practise.—*N. Y. Times.*

* * *

The late Dr. Stephen S. Colvin was the writer of an interesting article in a late number of *School Life,* in which he traces the history and development of psychological tests from the Binet-Simon, originating in 1905, to the form used at present, known as the Stanford-Binet tests, adapted by Lewis M. Terman.

* * *

A recent article on Russia states that Ivan Michurin, known as the "Russian Burbank," whose experimental garden was visited before the war by botanists from all over the world, has had to discontinue his scientific work and take up private employment in order to support himself. One of his latest achievements was the breeding of a pear so intensely sweet that he gave it the name of "substitute sugar."

* * *

Certain phenomena in connection with earthquakes, it has been found, cannot be recorded, even by seismographs, but they produce upon animals certain biological effects, frequently manifested before the shock is registered. Dr. Hans von Hentig, of Munich, has made a study of such effects and reports his results in a recent issue of the *Journal of Comparative Psychology.* He has found that some animals, before an earthquake, evince great restlessness; others, a striking lethargy; others peculiar mental disturbances. Even fish show great excitement. In Cuba tame house snakes are kept because they always flee into the open before earthquakes, thus warning the household.

* * *

Where the Dinosaur Hid Its Eggs is the title of an article of unusual interest in *Asia* for January. This is an account of the discovery of the ten million year old dinosaur eggs, found in Mongolia by the Third Asiatic Expedition under the leadership of Roy Chapman Andrews. These eggs are now on exhibition at the American Museum of Natural History in New York City.

* * *

That Samuel Butler, author of *The Way of All Flesh,* as good as prophesied the psychoanalyst, is the opinion of Robert Graves, writing in the London *Spectator.* "He looked forward to a time when crime and illness should be interchangeable terms; and the 'straightener' was to be a man to whom patients confessed their delinquencies, and who undertook to cure them."

* * *

Three late books on subjects of interest to physicians, and of special value to students taking up the study of medicine, are *The Coming of Man,* by Prof. John M. Tyler, a study of evolution; *Population Problems,* by Prof. Edward B. Reuter, of the University of Iowa, a discussion of world population from the sociological point of view; and *Studies in Evolution and Eugenics,* by S. J. Holmes, professor of zoology in the University of California.

* * *

Aromatics and the Soul is the striking title of a late book, the author of which is named Dr. Dan McKenzie. This volume might be described as a philosophy of smells, for the author has apparently made an inventory of the characteristic smells of all the chief cities of the world, classified them, and described them. When he himself has not visited a city and so had no olfactory impression of it, he quotes the sensations of other writers.

* * *

When the Soviet Government of Russia nationalized the property of the heirs of Chekhov, the dramatist, they found in a safety deposit box an unpublished play and a history of medicine in Russia.

* * *

An article in a recent issue of *Natural History* describes curious little creatures known as snow worms. They resemble tiny black eels and are frequently found on the snow-covered slopes of high mountain ranges. At about four in the afternoon they appear in millions on fields of dry snow and remain all night, probably feeding on minute algæ. As soon as the sun appears in the morning, they burrow back again into the snow.

* * *

Civilization and the Microbe is the title of a late volume by Arthur I. Kendall, published by the Houghton Mifflin Company. The author's contention is that "in reality civilization owes much to the microbe,"—that most microbic action is beneficent and essential for the maintenance of life on the globe, in spite of the fact that a comparatively small group of bacteria are hostile to mankind.

* * *

The last several months have brought forth a sizable group of interesting novels. Among these might be mentioned Conrad's *The Rover;* Swinnerton's *Young Felix;* Willa Cather's *Lost Lady;* May Sinclair's *Cure of Souls; The High Place,* by James Branch Cabell; *Antic Hay,* by Aldous Huxley; *The Centaur's Wife,* by Cyril Hume; *The Puppet Master,* by Robert Nathan; *J. Hardin and Son,* by Brand Whitlock; *Heart's Blood,* by Ethel Kelley; *The Sun Field,* by Heywood Broun; *Don Juan,* by Ludwig Lewisohn, and *North of Thirty-Six,* by Emerson Hough.

* * *

Interesting, if not particularly valuable as criticism, is the volume recently published by Seltzer entitled *Marcel Proust, an English Tribute,* by Joseph Conrad and Twenty Others. One of these critics finds Proust's writing of "the rarest beauty . . . poisonous as well as curious." Conrad says he "pushed analysis to the point where it becomes creative." Walkley finds his work to be "an extraordinarily minute psychometry."

Abstracts from Current Literature

GENITOURINARY DISEASES

The Risks of Prostatectomy.—Kenneth M. Walker (*Clinical Journal,* October 17, 1923) thus summarizes his conclusions: Where signs of obstruction exist operation is indicated, with as little delay as possible, since the persistence of this obstruction is a menace to the integrity of the kidneys. Even in the presence of associated lesions, such as those of the heart and lungs, prostatectomy offers a better chance than catheter life. Of all the dangers that may attend prostatectomy, those resulting from lesions of the kidney are the greatest. Operation is to be advised only after a careful investigation of the renal function. Where sepsis is present, or where there is reason to suspect the efficiency of the kidneys, it is advisable to perform the operation in two stages, first draining the bladder, and then, at a later date, enucleating the prostate. Operation should be advised in the earlier stages of enlargement when the symptoms are sufficiently severe to interfere with the patient's comfort or the residual urine is over two ounces. The fact that a certain percentage (about thirteen per cent.) of apparently simple prostates show, on microscopic examination, areas of carcinomatous changes, is an argument in favor of early operation, but it is not sufficient ground for removing every prostate that appears to be enlarged, although it causes no symptoms.

Warning Against the Use of Arsphenamine in the Treatment of Syphilis in a Hemophilic.—Jacob Rosenbloom (*Journal of Labratory and Clinical Medicine,* October, 1923) warns against the use of arsphenamine in hemophilia, citing the case of a colored man who had had continual bleeding from a tooth socket following a tooth extraction. His hemoglobin was forty per cent. red cells 2,300,000, and Wassermann four plus, with a history of an initial lesion fifteen years before. Transfusion was performed. As the bleeding did not stop following the use of horse serum and transfusion, an injection of 0.6 gm. arsphenamine was given, one hour after which all of the patient's gums commenced bleeding at an alarming rate, the hemoglobin falling to thirty per cent. The bleeding was controlled by the use of adrenalin compresses and another transfusion. It was impossible to check the bleeding by the usual means, and two weeks following the injection of arsphenamine, he died from anemia due to the hemorrhages.

Hereditary Syphilis.—Edward A. Morgan (*Canadian Medical Association Journal,* December, 1923) says that in dealing with the newborn luetic infant one must use discretion in the administration of salvarsan intravenously. If the child is markedly undernourished and anaemic, it is, as a rule, better policy to restrict one's treatment to the use of mercurial inunctions until such time as the general condition of the patient improves. Attention to the diet and maintenance of the nutrition of the young infant is quite as important as antiluetic medication. Needless to say, every effort should be made to maintain maternal nursing. Treatment of the nursing infant through the medium of the mother's milk has nothing to recommend it except ease of administration. Such treatment is both inadequate and ineffective. Persistent and regular treatment is one of the prime essentials to success. The greatest problem to be faced is the management of the Wassermann fast case—the child who reports for treatment usually with some tertiary manifestation and whose blood after two or three years' conscientious treatment is persistently very strongly positive. Such cases are, as a rule, symptom free, and the problem which demands solution is, Shall we continue intravenous therapy at the risk of producing arsenical poisoning, or shall we discontinue treatment and invite a return of symptoms such as those of cerebrospinal syphilis? Finally he says: "After four years' observation of such cases, I am becoming more and more convinced that the continuation of arsenical treatment for longer than two years is seldom if ever, advisable. The possibility of the disease causing serious trouble in later life is, I believe, greatly exaggerated, and my own experience is that the best plan of procedure consists in improving the child's general condition by intelligent dietetic, hygienic and tonic treatment, and in ignoring altogether the Wassermann reaction."

The Operative Treatment of Vesical Diverticula.—After an extensive study of vesical diverticula and the various methods of treating them surgically, J. Swift Joly (*Lancet,* September 1, 1923) arrives at the following conclusions: 1. Excision of the sac is the only rational treatment of vesical diverticula. 2. No single set operation is suitable for all cases. 3. If the case is complicated by prostatic or urethral obstruction, both conditions should be treated at the same sitting. When this course is not feasible, it is better to remove the diverticulum first, and treat the obstruction at a later sitting. 4. A preliminary cystotomy does more harm than good in most cases. 5. The presence of a calculus either in the bladder or in the sac is an indication for excision of the diverticulum. 6. As a rule the ureter lies in close relationship with the neck of the sac, and must be guarded from injury during the operation. 7. The contents of a diverticulum cannot always be evacuated by catheterization. The urine left behind after catheterization, often a considerable amount, the author calls "concealed residual." 8. The presence of concealed residual urine vitiates all tests of the renal efficiency which are carried out on bladder urine. To obtain an accurate estimate of the renal function it is necessary either to catheterize the ureters or to trust to an estimation of the blood urea. 9. The presence of a diverticulum is best diagnosed by means of the cystoscope, and its size and position ascertained by means of cystograms.

Gonococcal Vesiculitis.—David Watson (*British Medical Journal,* September 15, 1923) believes that the prevention of vesiculitis is the prevention of posterior urethritis and it can be insured once the anterior urethra has become infected only by local preventive treatment applied to the mucous membrane of the posterior urethra. All cases of gonococcal urethritis coming under treatment should as a matter of choice be subjected to treatment by the Janet irrigation method of treatment, using 1:8000 to 1:4000 solution of potassium permanganate, or, preferably, 1:400 acriflavine in physiological saline solution once in twenty-four hours. In cases of gonococcal urethritis which come under treatment after infection of the posterior urethra, the irrigation method of Janet is indicated in all except the hyperacute cases. No intraurethral instrumentation should be done in the acute stage, except in acute retention, which cannot be relieved otherwise. A suppository of one one-hundredth grain of atropine, twice daily, is useful in the prevention of complications. The treatment of the vesiculitis includes rest in bed, hot sitz baths and hot rectal irrigations, diathermy and atropine; vaccines are usually more harmful than helpful, but detoxicated vaccines are harmless and sometimes beneficial. Antigonococcal serums show variable results. Operation is occasionally required.

Salivary Urea and the Mercury Combining Power of Saliva: A New and Simple Index of Renal Insufficiency.—The following technic is advanced by Philip S. Hench (*Medical Clinics of North America,* July, 1923) for the test: The mouth is first washed out with water. A small piece of paraffin may be used to stimulate salivary flow, and two specimens of about eight c.c. each are collected. The first specimen, which removes food particles or excess of epithelial débris, is discarded or may be used as a check on the second specimen, which is used for titration. Five cubic centimetres of saliva are measured into a flask by means of a graduated pipette, and titrated with a five per cent. solution of mercuric chloride. The addition of bichloride of mercury is continued until one drop of the mixture, when added to a drop of saturated solution of sodium carbonate on a porcelain plate, causes a definite reddish brown tinge to appear promptly. Unless the brown color develops within about three seconds, this should not be considered the end point, and a drop or two of the bichloride should be added. For the sake of comparative uniformity the results may be reported in terms of cubic centimeters of bichloride of mercury required for each one hundred c.c. of saliva. This value is called the salivary urea index.

The concentration of urea in the saliva increases in approximately the same relationship as the blood urea concentration, although slightly lower figures are generally obtained. By means of this test it was observed that there

was a direct parallelism between the estimations of the mercury combining power of saliva and the estimations of blood urea. Its use is advocated as a routine procedure in the study of renal function, as an adjunct to the phenolsulphonephthalein test, and in place of the estimations of blood urea, when such estimations are not available. The values will not always agree absolutely, but will run parallel. The combined urea and ammonia nitrogen of saliva of normal persons is approximately from six to sixteen mg. for each one hundred c.c., representing from thirteen to thirty-three mg. urea for each one hundred c.c. of saliva. In urea retention the combined urea and ammonia nitrogen of saliva is increased in definite relationship to the increase of the blood urea nitrogen. The mercury combining power of saliva normally varies between thirty and fifty c.c. bichloride of mercury for each one hundred c.c. saliva; it increases with urea retention, and therefore this test may be used as a urea index.

GYNECOLOGY AND OBSTETRICS

Results in the Treatment of Abortion with the Oral Administration of Quinine.—Robert Poschacher (*Weiner klinische Wochenschrift,* August 9, 1923) was enabled to show that quinine is effective only in the uterus that is ready to undergo labor pains. The further the pregnancy has advanced and the more the abortion is in progress and the more the cervical canal or the cervical os is dilated, the better are the results with quinine. On the other hand, in incomplete abortion, the quinine acts the less, the smaller the placental remains which are left behind in the uterus and the more the uterus has returned to a state of rest. In incipient abortion the results were good in eighty-two per cent. of cases, whereas in incomplete abortion the results were good in only thirty per cent. Even if little or no success is achieved with quinine, it at least causes a dilatation of the cervical canal or it maintains the already acquired dilatation and thereby facilitates the emptying of the uterus, so that the uterus may be emptied in more than half of the cases without any dilatation. No injuries were observed to result from quinine; the associated unpleasant symptoms, such as tinnitus, a dull feeling in the head, and difficult hearing were only transient. This quinine was vomited rarely and only in highly febrile cases. The author believes that in every case of abortion, especially in the febrile cases, no curettage should be undertaken without previously having tried to empty the uterus with quinine.

Treatment of Acute Salpingitis.—Aleck W. Bourne (*British Medical Journal,* September 8, 1923) affirms that the mere recovery of the patient is not the only aim of treatment and that an attempt should be made to prevent sterility and also pelvic invalidism. He endeavors to accomplish this by the following line of treatment: 1, to prevent the spread of the acute disease and its extension to the the abdominal cavity proper; 2, to prevent the formation of chronic sequelæ in the shape of adhesive pelvic peritonitis, interstitial salpingitis, pyosalpinx, etc., and, 3, to enable the affected tube to resolve sufficiently to resume its normal function. The cardinal lesions requiring treatment are: 1, suppurative inflammation of the tubes, and later the ovaries; 2, suppurative pelvic peritonitis. The ideal is to arrest the destructive inflammatory process at the earliest possible moment by operating as soon as possible. The advantages of salpingostomy are as follows: 1, the spreading peritonitis and the formation of adhesions and peritoneal abscesses are checked; 2, the tube is drained and allowed to recover without the risk of further permanent changes; 3, it renders the formation of a pyosalpinx impossible, and permanent thickening of the tubal wall extremely unlikely. If after laying open the tube the mucous membrane shows gray patches of ulceration and gangrene, salpingectomy should be done. With early salpingectomy pregnancy is made possible, and if the tube is damaged too greatly salpingectomy will prevent invalidism.

Victor Bonney (*British Medical Journal,* September 8, 1923) believes that, contrary to the older teachings, early operation for acute salpingitis is not dangerous. While it is possible for an inflamed tube to recover sufficiently to be followed by pregnancy, such complete recoveries are rare. The author's experience with conservation of the tubes with drainage has not been particularly encouraging. If it can be shown that complete recovery of an inflamed tube is not uncommon, then the acutely inflamed tube must be conserved whenever possible, either by 1, not operating at all, or 2, conservative operation, either by simple drainage of the pelvis or by slitting and drainage. The author favors early operation.

W. Blair Bell (*British Medical Journal,* September 8, 1923) confines operative interference to posterior colpotomy in acute salpingitis to those cases in which a febrile reaction is present and in which pus is found in the pelvis. With pure gonococcus infections there is little danger to life and therefore surgical intervention may be tried in these cases. A number of mild cases of gonococcus salpingitis recover spontaneously. In most of the cases a cure is not likely to result from operation, inasmuch as the interstitial portion of the tube is usually occluded. Furthermore, the author doubts whether incision of the tube can lead to disappearance of the gonococci located in the mucosa.

Leonard Phillips (*British Medical Journal,* September 8, 1923) performed twenty reconstruction operations on the tubes in a series of twenty-five laparotomies. The operative technic included: 1, salpingostomy; 2, partial salpingectomy; 3, resection and anastomosis; 4, incision and resuture after canalization. Among these twenty cases, five pregnancies resulted. Except in one case no operation was performed more than two years ago. Three successes were in cases of bilateral salpingostomy, for closed club ended tubes—one in a case of bilateral resection and anastomosis, and one in a case of bilateral incision and suture after separation of adhesions with resection of one ovary. No successes have so far followed in cases of partial salpingectomy, and in operations performed at the uterine end of the tube.

Treatment of Prolapse of the Vagina in the Absence of the Uterus.—Of the various operative procedures used recently for the correction of a vaginal prolapse, the Neugebauer-Le Fort operation and its modifications have the disadvantage that they destroy the power of cohabitation and the various suspension methods require a certain length of the vaginal cul de sac. Ludwig Nürnberger (*Zentralblatt für Gynäkologie,* August 18, 1923), proposes a technic for cases in which suspension is impossible, whereby the power of cohabitation is preserved. If the uterus is absent a prolapse of the vagina can be corrected either by an operative elimination of the vaginal sac, which however does not prevent a recurrence if the defect in the floor of the pelvis is excessive so that the closed and destroyed vagina represents only a freely movable plate of fascia, or by suturing it to the anterior abdominal wall or to the promontory. But if the vagina is not sufficiently long, these methods are not applicable. In the case described by the author, a strip three cm. broad and ten cm. long was taken from the aponeurosis of the rectus abdominis muscle, the base of which was left in connection with the edge of the pelvis, and sutured to the upper edge of the posterior surface of the prolapsed cul de sac with silk sutures. Seven months after the operation the patient was very well satisfied with the operation. This technic is recommended for patients who desire preservation of the power of cohabitation.

Uterine Hemorrhage.—F. A. Cleland and Donald M. Low (*Canadian Medical Association Journal,* November, 1923) try to impress the following points:

1. The importance of impressing upon both the public and the profession that any abnormal uterine bleeding requires most careful investigation as soon as it appears.

2. The application of radium or x ray in gynecological cases should be under the supervision or be conducted on the advice of a physician or surgeon skilled in gynecological examination and diagnosis.

3. The decision as to the choice of treatment should not rest with the radiologist unless he is specially trained in gynecological diagnosis.

4. It should be an axiom that radium or x ray should not be used until an examination under anesthesia has been made, and if necessary, a diagnostic curettage or biopsy done.

5. Neither the surgeon nor the radiologist should have only one point of view.

6. The use of radium is contraindicated in cases of, 1, inflammatory lesions of the tubes or ovaries; 2, leiomyomata larger than a three and a half months' pregnant uterus; 3, large, pedunculated, subserous or submucous leiomyomata; 4, leiomyomata showing any form of degenerative change; 5, leiomyomata complicated by ovarian tumors; 6, leiomyomata producing marked pressure symptoms.

7. Radium should be used with great care in young patients in whom it is desired to retain active menstrual functions.

8. Radium is the treatment of choice in, 1, leiomyomata not larger than a three and one half months' pregnant uterus in women over forty years of age; 2, fibrosis uteri; 3, hyperplastic glandular endometritis; 4, polypi; 5, patients who are poor surgical risks.

9. The size of the dose depends upon, 1, the size of the uterus; 2, the age of the patient; 3, whether the function of childbearing is to be preserved or sacrificed.

10. Complications and unfavorable results are to be avoided only by a careful, discriminating, differential diagnosis.

Operative Treatment of Puerperal Bacillus Aerogenes Capsulatus Infection of the Uterus.—H. Brütt (*Zentralblatt für Gynäkologie,* August 18, 1923) states that this disease is met with much more frequently than is suspected and is not always properly interpreted. The author reports his seventh case, which was diagnosed clinically by a mass as large as two fists above the symphisis and by crepitation on palpation. The treatment consisted in extirpation of the uterus and of the right adnexæ. It had followed a previous criminal abortion. The local focus was apparent in this case and consequently the operation was indicated and led to a recovery. If, however, there is a general infection with the Fränkel bacillus an operation is superfluous and dangerous.

CLINICAL MEDICINE

Studies on the Relation of Tetanus Bacilli in the Digestive Tract to Tetanus Antitoxin in the Blood.—Carl Tenbroeck and Johannes H. Bauer (*Journal of Experimental Medicine,* April, 1923) found that the presence of tetanus bacilli in the digestive tract leads to the production of antibodies, which explains why tetanus infections are relatively uncommon in Peking, where a third of the population carry these organisms. Twenty-six such carriers showed considerable amounts of antitoxin in their sera, while with two exceptions, thirty individuals whose stools showed no tetanus bacilli showed sera free from tetanus antitoxin.

Influence of Calcium Chloride Upon Experimental Botulism.—Ivan C. Hall and Nelson C. Davis (*Journal of Experimental Medicine,* April, 1923) performed the work reported to study the action of calcium chloride in initiating socalled defense rupture to Bacillus botulinus. No such action has been demonstrated, although the doses given were sufficiently large to cause induration and in some cases sloughs by the subcutaneous route. Treatment of Bacillus botulinus with alcohol has been found markedly to decrease its toxicity for guineapigs, which confirms the work of Bronfenbrenner and Schlesinger. Toxin free spores of Bacillus botulinus have been found pathogenic for guineapigs.

Studies of Urinary Acidity.—N. R. Blatherwick and M. Louisa Long (*Journal of Biological Chemistry,* October, 1923) cite experiments to demonstrate that the increased acidity of the urine which is produced by eating prunes and cranberries is due to the synthesis and excretion of hippuric acid. The greater portion of this hippuric acid is derived from sources other than benzoic acid, and quinic acid is the most probable compound concerned in this synthesis.

Some Observations on the Creatinine Excretion of Women.—Laura McLaughlin and Katherine Blunt (*The Journal of Biological Chemistry,* November, 1923) report that the creatinine excretion of women is well within the range Shaffer reported for normal men (5.7 to 11.7 mg.) The creatinine coefficient for underweight women is apparently much higher than for normal women. Comparison of the day and night excretions of creatinine per hour showed no constant difference. The results obtained in this series of experiments indicate no relation between high protein diet and creatine excretion. Creatine was found to be an almost constant component of the day urine of one healthy woman.

Influenzalike Bacilli Isolated from Cats.—T. M. Rivers, and Stanhope Bayne Jones (*Journal of Experimental Medicine,* February, 1923) in examining the cultures from the throats of fifty normal cats in February, 1922, noted a number of colonies of gram negative, nonmotile bacilli on the rabbit blood agar plates, which looked like those of influenza bacilli. Seven strains were selected for study. They did not grow on ordinary media, but will do so on a medium to which an autoclave labile substance has been added as an accessory growth factor. These bacilli are similar to Bacillus parainfluenzæ in man. One strain was more exacting in its food requirements than Bacillus influenzæ and for convenience has been placed for the present in the parainfluenza group.

Reverse Selective Bacteriostatic Action of Acid Fuchsin.—John W. Churchman (*Journal of Experimental Medicine,* January, 1923) defines reverse selective activity as a bacteriostatic property whose selective feature is the reverse of that of gentian violet. Acid fuchsin was found to possess this bactericidal power, selective as between gram negative and gram positive aerobic organisms. The property was also possessed by simpler sulphonated substances and appears in some way dependent on the presence of SO_3 radicals. Bacillus pyocyaneus, an organism resistant to gentian violet, and one which causes persistent and annoying wound infection, is quite susceptible to acid fuchsin. The observations on the effect of sulphonated substances may give a lead as to the control of these infections.

A Fatal Case of Bacillus Acidi Lactici Meningitis with Autopsy Findings and Review of Bacillus Mucosus Infection.—Henry M. Ray (*Journal of Laboratory and Clinical Medicine,* January, 1923) reports the only case on record in the literature in which the Bacillus acidi lactici has been isolated from the spinal fluid. In the case described it was isolated twice each from the blood and spinal fluid during life. The patient presented the classical signs of meningitis, and the pathogenicity of the organism was demonstrated by its virulence for rabbits and guinea pigs. Death occurred after a twenty-eight day illness in the hospital, and the organism was also isolated from the brain, spleen and liver.

Copper as a Constituent in Woman's and Cow's Milk.—Alfred F. Hess, G. C. Supplee, and B. Bellis (*Journal of Biological Chemistry,* October, 1923) found that a sample of raw cow's milk contained 0.05 mg. of copper per litre, while three samples of pasteurized milk showed somewhat higher values, 0.6, 0.7 and 0.6. Two samples of human milk showed 0.4 and 0.6 mg. per litre. Infants therefore consume regularly small amounts of copper with their food. An examination of the urine of infants showed that copper is absorbed from the alimentary tract, as proved by its constant presence in the urine.

Alkali Reserve of the Blood Plasma During Protein Shock.—A. A. Eggstein (*Journal of Laboratory and Clinical Medicine,* June, 1921) used secondary proteoses and typhoid bacteria, given intravenously, as the toxic substance to produce shock in dogs. The animals showed a rapid and continuous decline in the alkaline reserve of the blood, and there was a definite relation between this and the lowered blood pressure in toxemic shock. The animal's life is in danger when the alkali reserve of the blood falls below thirty volumes per cent. Sodium carbonate given before the injection of a toxic protein prevented the carbon dioxide from reaching as low a level as in the untreated animals, and the alkali reserve which has been lowered in protein shock may also be restored by the intravenous administration of sodium bicarbonate, which apparently relieves distressing symptoms.

Studies in Carbohydrate Metabolism.—Frank P. Underhill and Gustav Wilens (*Journal of Biological Chemistry,* November, 1923) in order to determine the influence of a definite kidney lesion on the blood sugar content, produced experimental tartrate nephritis in normal fasting rabbits by subcutaneous administration of sodium tartrate in doses of fifty to seventy-five mg. per kilo. Following this there is a state of hyperglycemia in rabbits, and at times there may be increased kidney function as far as the elimination of sugar is concerned, Thus, the threshold to sugar appears to be alternately raised and lowered in tartrate nephritis. An injection of glucose results in a still higher elevation of blood sugar, which is in excess of that noted with tartrate alone.

Cross Fixation of Syphilitic Antigen by Tuberculous Sera.—Robert A. Kilduffe (*Journal of Laboratory and Clinical Medicine,* November, 1923), examined the sera in 104 cases of pulmonary tuberculosis in varying stages of activity, by the quantitative method of Kolmer. From the results obtained, there appears to be little support for the assumption that tuberculosis *per se* can give rise to a false positive complement fixation reaction with syphilitic antigens, and such positive reactions, when obtained in tuberculosis, necessitate an exhaustive examination for evidences of coincident syphilis.

Preservation of Blood for Chemical Analysis.—F. V. Sander (*Journal of Biological Chemistry,* November, 1923) advises using a mixture of 0.01 gm. of sodium fluoride and 0.001 gm. of thymol for each c.c. of blood in order to preserve it, so that an immediate analysis is not necessary. The values for nonprotein nitrogen, urea, uric acid, creatinine, creatine, and sugar will have the same clinical significance as those values obtained by an immediate analysis of the blood. The urea, uric acid, creatinine, creatine and sugar content of the blood can be kept constant for at least two weeks. The increase in nonprotein nitrogen value cannot be accounted for by an increase in ammonia and amino-acid content.

Studies on Diazoreaction.—N. Malmberg (*Acta Pædiatrica,* July, 1922) states that positive diazoreaction was observed in seventy-three per cent. of his cases of measles. The reaction lasted from one-half to eight days. It usually developed two to four days after the eruption of the exanthema, in a few cases simultaneously with the eruption, and in no case before the eruption. The reaction was at its height when decrease in temperature began. Positive reactions with a febrile temperature were often observed. A real connection could be traced between the leucocyte count of the blood on one hand and the diazoreaction on the other; a decrease in leucocytes was usually accompanied by positive reaction, and the rise in leucocytes usually occurred simultaneously with the disappearance of the diazoreaction.

Studies on Lymphoid Activity.—Relation between the time and extent of lymphoid stimulation induced by physical agents and the degree of resistance to cancer in mice.—James B. Murphy, Waro Nakahara, and Ernest Sturm (*Journal of Experimental Medicine,* April, 1921) report experiments in which mice were subjected to treatment with x rays or dry heat to stimulate the lymphoid cells. The animals were divided into two groups, the first of which received the treatment seven days before, and the other immediately before inoculation with cancer. The resistance of mice inoculated with cancer immediately after a stimulating dose of x rays is no higher than that of normal mice, and sometimes lower, while those inoculated with cancer a week after a stimulating dose of x rays showed a consistently higher degree of resistance, both in the number of takes and in the rate of growth of the tumor. The mice inoculated immediately after heating showed a definitely higher resistance than in the controls, while those heated a week prior to inoculation showed even a higher degree of immunity. The degree of immunity to the transplanted cancer seems to depend on the amount of lymphoid stimulation existing either at the time of, or following soon after the cancer inoculation.

MALIGNANT GROWTHS.

Relation of Carcinoma to Infection.—W. M. Ford Robertson (*Lancet,* August 18, 1923) examined a series of fifteen cases of various types of malignant disease with the following results: The anaerobic diphtheroid bacillus was demonstrated in cultures from all of the fifteen cases. In seven cases the bacillus was obtained subsequently in pure cultures in sufficient quantity for vaccines to be prepared and used therapeutically. In all the fifteen cases a mannite nonfermenting staphylococcus was isolated, and in about two thirds of the series streptococci were present also. In nearly every instance these staphylococci and streptococci were obtained only on anaerobic cultures. In one case subcutaneous fat, and, in another case, muscle of patients who were not the subject of malignant disease, gave negative results for the anærobic diphtheroid bacillus.

Cancer of the Breast.—Cecil Rowntree (*British Medical Journal,* May 5, 1923) says that there is no absolutely pathognomonic sign of cancer of the breast, but there is a sign of overwhelming significance, namely, the adhesion between the growth and the skin overlying it—not the coarse and obvious infiltration met with in advanced cases, but a much more delicate involvement, resulting in a faint dimpling of the skin which is often so slight that it may be visible only after careful examination in suitable conditions of light. In its earliest stages it can be made to appear by grasping the breast on each side of the suspicious nodule and trying to push the skin away from the tumor. By then looking along the surface of the breast it may be possible to perceive slight irregularity in the contour not hitherto apparent. If this sign be evident the author is convinced that a definite diagnosis of malignancy may be safely made with the utmost confidence, irrespective of the presence or absence of retraction of the nipple, alteration in the size and shape of the breast, enlargement of glands, or any of the other classical signs of cancer. On the other hand, absence of adhesion to the skin does not necessarily indicate that the tumor is benign, for the growth may be too small, or, if the breast be large and fat, the distance to the skin may be too great. The author prefers the Handley operation for cancer of the breast, adapted to the individual case.

Abdominal or Vaginal Operation for Carcinoma of the Cervix.—Josef Halban (*Zentralblatt für Gynäkologie,* September 15, 1923) believes that the abdominal and vaginal methods of attack on carcinoma of the cervix are of exactly the same value. Consequently the route of attack may be left to the ability and experience of the individual surgeon. However, the author is impressed by the fact that with a happy combination of the use of both methods the results in the treatment of cancer of the uterus may be considerably improved, particularly when certain patients, such as those with unusually thick abdominal walls and those unsuited to the Trendelenburg position because of internal complications in which laparotomy is most dangerous, are operated upon by the vaginal route.

Carcinoma of the Esophagus.—Porter P. Vinson (*American Journal of the Medical Sciences,* September, 1923) presents the following conclusions from a study of 154 patients at the Mayo clinic: 1. The incidence of carcinoma of the esophagus is higher than is generally believed. 2. The symptoms are ordinarily quite characteristic and their duration from onset to death is one year. 3. Men are much more susceptible than women, the ratio being five to one. 4. Carcinoma of the esophagus is rare is persons under forty years. 5. In men the lesions are most common in the middle third of the esophagus, whereas in women the growths predominate in the upper third. 6. Demonstrable metastasis is infrequent but occurs more often with lesions of the introitus and, therefore, is proportionately more common in women. 7. Previous trauma to the esophagus is not a definite factor in the causation of malignant esophageal disease. 8. The history of the case and the cautious passage of sounds are the most valuable factors in making a correct diagnosis. 9. The röntgenogram is of value in making a diagnosis, but is not infallible. 10. The esophagoscope is of limited value in diagnosis and treatment. 11. The mortality in untreated cases is one hundred per cent., and surgery offers little as a curative or palliative measure. 12. Radium or röntgen ray therapy is practically valueless. 13. Forcible dilatation of the malignant stricture gives greater relief than any other form of treatment.

Early Diagnosis of Cancer of the Stomach by Means of Gastric Analysis.—T. Izod Bennett (*British Medical Journal,* August 18, 1923) maintains that free hydrochloric acid is secreted by the stomach in the majority of patients with gastric carcinoma and that even in the presence of complete achlorhydria the gastric analysis rarely reveals the same findings as in pernicious anemia, chronic gastritis, or other forms of benign achylia. With the proper preparation of the patient the night before, and with careful gastric analysis of the fasting gastric contents on the following morning, evidence of stagnation, or of hemorrhage with pathological secretion, or both, will be found in the vast majority of cases of gastric carcinoma, which evidence is usually distinguishable from that of other diseases. The results of gastric analysis should not be interpreted on empirical or purely chemical grounds. Early carcinoma of the stomach can be detected by the evidence of stagnation, as by giving two teaspoonfuls of finely divided particles of charcoal in a glass of milk over night, with possibly an additional charcoal biscuit. The contents of the fasting stomach must then be evacuated carefully. Of fifty-three patients with gastric carcinoma examined, charcoal was demonstrable in the fasting gastric contents in thirty; signs of stagnation, such as foul odor, lactic acid, and a relatively high acid content other than hydrochloric acid, were found in twenty of the remaining twenty-three patients. Fresh or degenerated blood was found in thirty-five patients. The author did not find a single case of gastric malignancy which did not give a characteristic picture on gastric analysis and the only condition resembling it is gastric syphilis, in which there may be tumor formation with obstruction at the pylorus which is distinguishable from carcinoma only by histological examination. The Wassermann reaction is positive in these cases but not reliable.

Medicolegal Notes.

MERE WRONG DIAGNOSIS AND FAILURE TO CURE NOT ACTIONABLE

In an action for alleged malpractice, the theory of the complaint was negligence in making a wrong diagnosis and giving treatment accordingly, treating plaintiff's arm with vaccine for a supposed disease of the flesh and blood, instead of performing a surgical operation to remove infected bone. The evidence showed that the defendants were properly qualified and there was no evidence that any means of diagnosis used by them were improper, or that the exercise of care required the use of any other means in deciding what was the matter with the plaintiff's arm and how it should be treated. Plaintiff's own witnesses testified that the treatment adopted would have been proper for the disease of the soft tissues which defendants diagnosed plaintiff's ailment to be. But three expert witnesses testified that, in their opinion, upon certain facts which some of the evidence tended to prove must have been learned by defendants from the history of the case and their examination, the plaintiff had acute osteomyelitis, requiring a surgical operation; while six expert witnesses testified that upon those facts, in their opinion, the plaintiff was not afflicted with osteomyelitis when defendants were treating him for infection of the tissues, but that the treatment which was given was proper for what he really was afflicted with. The Indiana Supreme Court held, Edwards v. Uland, 140 N. E. 546, that the evidence did not make a case of negligence in making a wrong diagnosis.

Assuming, however, that the plaintiff was afflicted with osteomyelitis from the beginning and that the defendants were mistaken in their diagnosis, it was held that such facts alone would not give him a right to recover damages. A physician or surgeon is not an insurer, and does not bind himself to make a correct diagnosis and effect a cure or to respond in damages. He is only bound to possess reasonable skill and to use ordinary care, and if he makes a mistake in his conclusion as to whether a sore place on the skin has its origin in the flesh or in the bone under the flesh, he is excused from liability if, possessing reasonable skill, he has used ordinary care in making an examination, and has honestly reached the mistaken conclusion by the use of such skill and such care. In the absence of evidence of any lack of care in making the examination and forming his judgment, mere proof that the diagnosis was wrong will not support a verdict for damages. Not having warranted a cure, if he has reasonable skill and learning and uses ordinary care, he is not liable for the consequences of an honest mistake of judgment. A failure to cure is not enough, in itself, to raise an inference of negligence in the diagnosis and in the treatment adopted.

An instruction to the jury, that if a physician fails to use his unbiased judgment in diagnosing disease and allows any ill feeling toward another physician to bias his judgment or influence his treatment, and such action results in injury to the patient, the physician is liable, was held outside the issue and erroneous.

Judgment for plaintiff was reversed and a new trial ordered.

DRUGLESS HEALERS MUST PROCURE LICENSE IN OKLAHOMA

In proceedings against a socalled drugless healer for practising medicine without a license as required by the Oklahoma statutes, the proof showed and the defendant admitted that he maintained an office in Oklahoma City where he held himself as a person competent to treat those afflicted with various physical infirmities for a fee; and witnesses testified that he had advised them to use an epsom salts solution as an eye wash. This the defendant denied.

The accused claimed he was not practising medicine within the meaning of the statute, but that his system of drugless healing was to use nature's remedies to purify the blood and to stimulate the different organs of the body by physical culture and proper food selection and by fasting. It appeared that he also practised psychic suggestion.

Accused was convicted of practising medicine without a license in violation of section 8815, Comp. Stat., 1921. Another section, 8818, provides that any person claiming to practise any drugless system of healing must have attended a reputable college for a period of not less than twenty-seven months and passed examinations in anatomy, chemistry, bacteriology, pathology, surgery, physical diagnosis, etc. It appeared that the accused could not legally qualify as a drugless healer any better than as a regular practising physician. He admitted that he had made no attempt to comply with either of these statutes. Judgment of conviction was therefore sustained. Feige v. State, Oklahoma Criminal Court of Appeals, 215 Pac. 437.

REQUIREMENTS IN OHIO FOR PRACTICE OF LIMITED BRANCHES OF MEDICINE AND SURGERY

By the provisions of section 1274-2, Ohio General Code it is required that persons desiring to practice limited branches of medicine and surgery without preliminary examination shall establish to the satisfaction of the State Medical Board the fact of having actually practiced those limited branches for the full period of five years continuously prior to October 1, 1915. The affidavit of the applicant of his having had such practice is not conclusive upon the board. State ex rel. Copeland v. State Medical Board, 107 Ohio St. 20, 140 N. E. 660.

QUESTION OF NEGLIGENCE IN TREATMENT OF BROKEN FEMUR HELD FOR JURY

In an action against a hospital association by a patient it appeared that the plaintiff sustained a broken femur, and part of the treatment at the hospital consisted of pressure upon the fractural parts by means of a wire screen device shaped like a legging, the pressure being adjusted by loosening or tightening straps as the condition of the leg seemed to require from time to time. The adjustment of the pressure was left to the patient who was bedfast and in a badly crippled condition. The Nebraska Supreme Court, Doty v. Lutheran Hospital Assn., 194 N. W. 444, on appeal from a directed verdict and judgment for the defendant, holds that whether the leaving of the adjustment to the patient constituted negligence was a question of fact which should have been submitted to the jury.

The broken femur was examined by the surgeon only three times in seven weeks and a day, when the patient was sent home. Whether the infrequency of the examination constituted negligence was also held a question for the jury.

The patient contracted smallpox at the hospital, which was known to the physician who sent him away, but without informing the patient. Whether failure to caution the patient or instruct him as to the care he should observe in his contact with his family, one of whom became infected with the same disease, was negligence, was also a question of fact for the jury. The judgment was therefore reversed, for a trial on the merits.

Disseminated Tuberculosis*

Caseous Tuberculosis of the Thymus and Myocardium

WILLIAM J. CARSON, M.D.,
Baltimore, Md.

Tuberculosis of the myocardium is comparatively rare. Laennec (1) in 1826 assigned tuberculosis of the heart as thirteenth in rank among the organs affected but gave no instance. To Townsend (2), of Dublin, belongs the honor of reporting the first case of myocardial tuberculosis in 1832. Haberling (3) in 1865 was able to collect twelve cases. (Some of these cases were pericardial only.) Sanger (4) in 1878 gathered from the literature and classified twenty-two cases including three of his own and omitted several doubtful cases. Valentine (5) in 1895 published a monograph with a summary of thirty-six reported cases.

Other cases have been reported by Mendez (6), Labbe (7), Barie (8), Kaufman (9), and others, which were summarized in a thesis by Fuchs (10) in 1898, which included two of his own, making a total of fifty-three cases. Anders (11) in 1902 gave a complete review of the literature and collected twelve additional cases, and added one case of his own, making seventy-two cases reported. Koch (12) in 1917 reported a case of conglomerate tuberculosis in the myocardium with pericarditis which was probably of the bovine type. Binder (12) in 1920 reported a case in the left auricle. Leuscher (14) in 1921 reported two cases. Massini (15) in 1921 added one case. Adding the case herewith reported makes a total of seventy-eight cases.

TUBERCULOSIS OF MYOCARDIUM

Tuberculosis of the myocardium, according to the studies of the authorities herein noted, appears in three types:

1. Tubercles, single or multiple, from pea to goose egg size (Binder) which may project beneath the endocardium or pericardium or be buried within the myocardium. In the majority of cases they consist of firm, whitish masses with caseous centres.

2. The miliary variety, in which grayish semi-transparent masses project as minute elevations beneath the endocardium. These occur most commonly on the ventricular wall.

3. The diffuse form of tuberculous infiltration, which consists of a more or less general diffuse tuberculous infiltration of the myocardium and is usually seen in connection with tuberculosis of the pericardium.

Tuberculosis of the myocardium most frequently occurs in the right ventricle, next in frequency is the right auricle, with but few cases occurring in the left side. The large tubercles occur most frequently, and the miliary variety is second in frequency. It is practically always secondary to tuberculosis elsewhere in the body. Demme (16) in 1886 reported a case in which no other tuberculous lesions were found in the body. Binder's (13) case of tuberculous tumor of the left auricle showed no other involvement of tuberculosis. In Massini's (15) case the tubercle bacilli, human type, were demonstrated in the myocardium and could not be found elsewhere in the body, and a careful histological search failed to reveal any other tuberculous lesion in the body. It occurs more frequently in males at any age, and the majority of cases reported occurred during the nursing age.

TUBERCULOSIS OF THYMUS

Tuberculosis of the thymus is apparently rare as a search through the literature reveals few cases reported. Demme, Vogel, Carpenter (17), Tixier, Feldzer (18) and others have reported cases occurring from forty-two days (Demme) to thirty-five years (Tixier and Feldzer). There are three varieties: caseous, miliary, and sclerotic. Primary tuberculosis of the thymus has been reported by Demme, who proved his case by animal inoculation, with no other lesion in the body. Vogel has reported a similar case. Tuberculosis of the thymus is usually caseous, and secondary to tuberculosis of hylic lymph nodes or lungs. In some cases only one lobe is involved.

REPORT OF A CASE

CASE.—The patient, a black male, aged eight months, was admitted to the University Hospital on February 27, 1922, with a history of having been a breast fed infant, delivered normally, weight at birth seven pounds, and apparently well up to the age of six months, at which time a cough developed which was continuous, and he breathed through the mouth. He cried when touched and slept a great deal. He had had a spasm four weeks previously and vomited about every day.

AUTOPSY

The body was that of a black child, measuring 66.5 cm. in length and weighing 4.8 kilo. It was emaciated. Rigor mortis was present. Postmortem lividity was confined to the dependent parts. The sagittal sutures were open and their edges rough in outline. The fontanelles were open and bulging. There was a large mass in the lower outer margin of the right eye, which was rather firm in consistency and appeared to be attached to the periosteum. There were three nodules on the scalp, one over each ear (one cm. above the ears) and one on the left parietal bone. These nodules were about two cm. in diameter and all appeared to be attached to the periosteum. At the angle of the right jaw, there was a nodule, irregular in outline, and the tissue showed marked bulging at that point. On the left side of the inferior maxillary there was a small nodule about one cm. in diameter. The right pupil was five mm. in diameter, the left four mm. in diameter and partially covered by a small scar which measured one by three mm. There were two teeth in the lower jaw. The lymph nodes of the neck were palpable, especially those in the left supraclavicular region, which were removed.

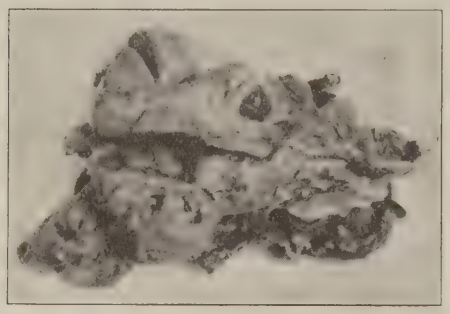

Fig. 1

Fig. 2

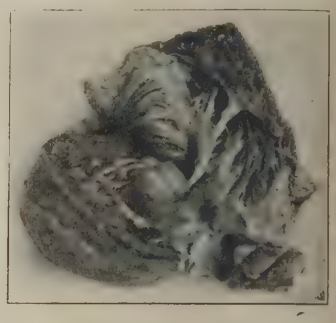

Fig. 3

Fig. 1.—Thymus with hylic lymph node attached (lower left corner) which was also attached to apex of right lung.
Fig. 2.—Heart showing grayish white nodule in left ventricular wall, four mm. in diameter.
Fig. 3.—Heart showing large grayish white nodule projecting into the right ventricle.

The muscles of the extremities were poorly developed, which gave the joints the appearance of being large in proportion to the shafts of the bones. There was a distinct left curvature of the vertebral column beginning at the fourth thoracic and extending down to the first lumbar vertebra.

On section, the subcutaneous fat was found to be scant. The peritoneum was smooth and dull in appearance throughout. The mesenteric lymph nodes were enlarged, firm and grayish white. There was one smooth, grayish white nodule on the serosa of the bladder—posterior surface. The proximal end of the appendix was bound down by adhesions. There was no free fluid in the peritoneal cavity.

The thymus extended down to the lower border of the third rib and was very firm in consistency, and there was a large hylic lymph node attached to it on the right, which was also very firm and measured 1.5 by 1 by .9 cm.

Heart.—The heart weighed thirty-five grams. The pericardial cavity contained about five c. c. of clear straw colored fluid. The parietal and visceral layers were everywhere smooth and glistening. The coronary vessels were distended with blood. On section there was found a grayish white nodule in the left ventricular wall measuring four mm. in diameter, firm in consistency. There was a large grayish white nodule projecting into the right ventricle, which occupied the space of the middle segment of the tricuspid valve. The tricuspid valve measured 2.5 cm.; pulmonary 2.6 cm., mitral 4 cm.; aortic 2.7 cm. Left ventricular wall 10 mm., right ventricular wall 3 mm.

Pleural cavity.—The left pleural cavity was free from adhesions and contained no fluid. The right pleural cavity contained no fluid, and there were some adhesions between the apex of the right lung and the lymph node which was also adherent to the thymus.

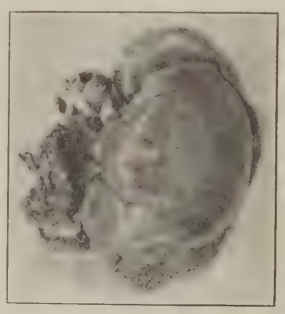

Fig. 5

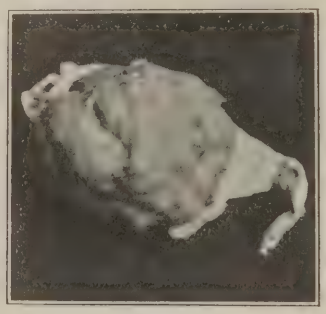

Fig. 6

Fig. 5.—Kidney showing three yellowish white nodules varying in size from .5 to 1 cm.
Fig. 6.—Nodule measuring 2.3 by 1.6 by 1.5 cm. attached to the dura in the posterior fossa on the right side.

Lungs.—The left lung was pale red with areas of a deep red mottling in the lower lobe. The pleural surface was smooth and dull in appearance, and there were a number of small nodules which could be felt throughout each lobe. On section it was of a pale reddish color mottled with small areas of a yellowish white color, which were firm in consistency and measured from one mm. to one cm. in diameter. The alveolar walls could be made out in a few areas and a small amount of frothy fluid could be squeezed from the terminal bronchi. The peribronchial lymph nodes were swollen and soft in consistency.

The upper lobe of the right lung was of a dark red color mottled with yellowish areas. It was firm in consistency throughout. The yellowish areas appeared as nodules of varying size from one mm. to 1.5 cm. There were a few tags of fibrin at the apex.

The lower and middle lobes were of a pale red color with the pleural surface dull, and with a few grayish white nodules on the surface, which varied in size from .5 cm. to .8 cm. On section the upper lobe was of a dark red color studded throughout with grayish white or yellowish firm nodules, irregular in out-

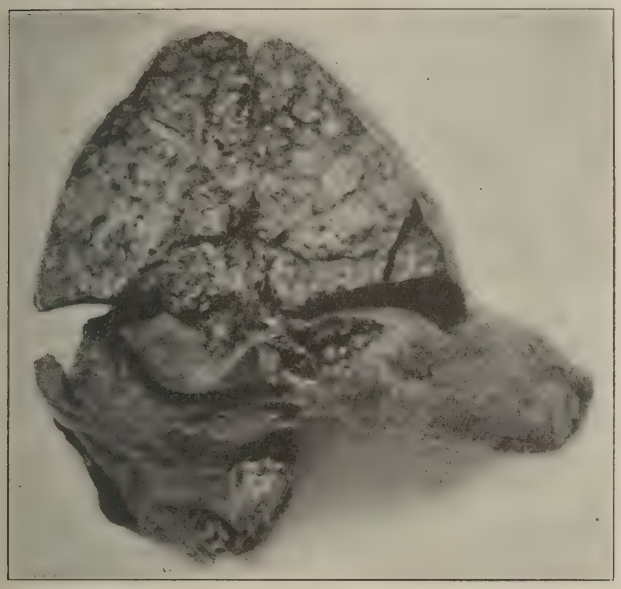

Fig. 4.—Lung showing caseous tuberculosis.

line. The alveolar walls could not be made out. The walls of the bronchi were thickened. There was no area which was air containing. The middle and lower lobes were of a pale pink color with the alveolar walls slightly visible in some areas, and they contained a number of nodules of a yellowish white color, which varied in size from one half to one cm. The peribronchial lymph nodes were enlarged and soft in consistency.

Spleen.—The spleen weighed thirty-five grams and measured six by four by two cm. It was of a pale reddish blue color studded with yellowish white nodules. The capsule was rough and the areas between these nodules of a pale bluish red color. It was firm in consistency. On section it was of a dark red color and the Malpighian bodies could be made out. There were a number of small, irregular, yellowish white nodules throughout, which varied in size from two mm. to six mm.

Stomach.—The muscular wall, submucosa and mucosa showed no gross pathological changes.

Duodenum.—The duodenum showed no gross pathological lesions.

Ileum.—In the ileum there were a few small grayish nodules in the mucosa, which varied in size from two mm. to six mm. The mucosa was smooth and distinctly made out.

Liver.—The liver weighed 200 grams and measures 12.5 by 8 by 4.7 cm. It was of a pale yellowish red color, and on the surface there were a few small grayish white nodules, which varied in size from one mm. to three mm. On section it was of a pale brownish yellow color. The liver lobules could be distinctly made out. There were a few small grayish white nodules scattered throughout the liver substance.

Gallbladder.—The mucosa was distinctly made out and there were no visible changes in the muscular wall.

Adrenals.—The adrenals on section showed, in the cortical portion, a small grayish white nodule, two mm. in diameter; the remaining portion of the cortex and medullary portions showed no changes.

Kidneys.—The right kidney weighed forty grams and measured 6.5 by 3.5 by 2.5 cm. The left kidney weighed ninety grams and measured 6 by 3 by 2.5 cm. The capsules stripped off with ease and left a pale smooth surface. The lobulations were distinct, and there were found on the surface of each kidney three yellowish white nodules, irregular in outline, varying in size from .5 to 1 cm. On section the cortex was found to be of normal thickness and the normal striations could be distinctly made out. The Malpighian pyramids could be seen. On the cut section, there were two yellowish white nodules, irregular in outline and appeared the same as those on the surface. The pelves and ureters showed no changes.

Pelvic organs.—On the serosa of the posterior wall of the bladder there was one small yellowish nodule. On section the mucosa was smooth and glistening throughout and showed no changes. The prostate showed no gross pathological changes. There were large yellowish gray nodules which occupied partly the testis and partly the vas deferens.

Neck organs.—The thymus was large and firm in consistency. On section it consisted of large nodules which were irregular in outline and occupied practically all of the thymic tissue. The lobulations could be made out. The centre of the nodule in the thymus was soft in consistency. The hylic lymph node on the right side, measuring 1.5 cm., was of

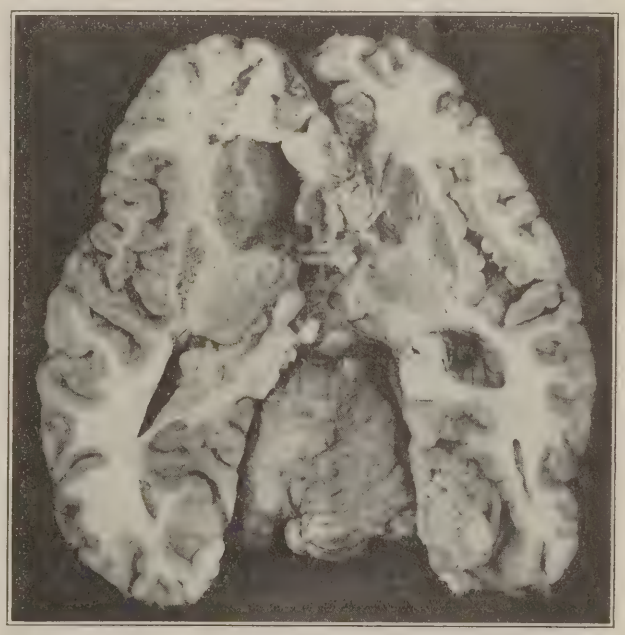

Fig. 7.—Brain.

a yellowish white color, and on section contained soft caseous material.

Head.—The mass at the external angular process of the frontal bone was adherent to the periosteum and measured three by four cm., and on section showed a wall composed of thick fibrous tissue, and

contained about four c. c. of a thick yellowish material. There were nodules on each lower temporal region of the parietal bone, which eroded through the bone and were of a distinct yellowish white color; the bone was soft and brittle.

Brain.—(I am indebted to Dr. C. L. Davis for the description of the brain.) There was an irregular grayish yellow nodule attached to the dura in the posterior fossa on the right side. It measured 2.3 by 1.6 by 1.5 cm. and pushed into the substance of the posterior pole of the occipital lobe on the right, and involved the occipital bone beneath it. The brain on section showed the following areas to be involved with soft yellow caseous tubercles. In a general way the infection had followed the course of the corpus callosum. The entire body of this structure was involved.

In the right hemisphere, on the right side the infection passed over the body of the lateral ventricle and the roof of the posterior horn, and reached the surface of the posterior limb of the postparietal gyrus. Ventrally it extended over the roof of the anterior horn, reaching the medial surface of the hemisphere at the gyrus rectus, two cm. from the frontal pole.

In the left hemisphere, the process extended dorsally over the roof of the posterior horn, reaching the medial surface of the occipital lobe in the region of the cuneus. Ventrally it passed forward over the body and anterior horn of the lateral ventricle and reached the superolateral surface near the frontal end of the middle frontal gyrus. A separate nodule about one and a half cm. in diameter was situated in the inferior postcentral gyrus. The septum pellucidum and the columns of the fornix were also involved.

Cerebellum.—A large area of the right lobe of the cerebellum was involved, extending from the surface of the anterior crescentric lobule close to the vermis of the lateral part of the inferior semilunar lobule.

Anatomical diagnosis.—Disseminated tuberculosis; caseous tuberculosis of lungs and mediastinal lymph nodes; tuberculosis of intestine and mesenteric lymph nodes; tuberculosis of ventricular wall—left, and middle segment of tricuspid valve; tuberculosis of liver, spleen, adrenals, kidneys, testis and thymus; tuberculosis of dura, brain and skull bones, ribs and vertebra.

Bones.—Femur, skull and rib; bone lacunæ very large and conglomerated. Canals all widened and many full of blood pigment. Skull a necrotic (caseous) mass, erosion of bone; bone cuts easily. There were no lime salts. Bone was fibrillar; it was very cellular in places—nuclei elongated oval. There was necrosis (caseation in areas). The fibrous structure was infiltrated densely with epithelioid and round cells. The hard bone structure was very porous, hemorrhagic. Haversian canals dilated and full of loose connective tissue with small round cells and epithelioid cells. Tubercle bacilli were seen in the granulations about caseous material.

Microscopical examination of tissues named above showed the presence of tubercles, a few of which contained giant cells.

I am indebted to Professor Hugh R. Spencer, director of the laboratory, for the privilege of reporting this case.

Vincent's Angina

JAMES H. HUTTON, M.D.,
Chicago

Vincent's angina is a term and condition long known to medical literature. It is not extensively described and from the literature one gets the impression that it is a rare condition and of little significance. My own experience leads me to believe that it is not a rare condition and the case herewith reported shows that it is not always a trivial affair by any means. The following is a review of dental and medical literature on the subject with the recital of a case of unusual severity. The treatment outlined is regarded as the best in the present state of our knowledge.

The term, Vincent's angina, was originally used to indicate the infection of the tonsils by Vincent's spirillum and fusiform bacillus whose symbiotic and anaerobic characteristics are well known, and was gradually extended to include the invasion of the tissues of the mouth, especially the gums. The dentists are said not to have been familiar with the condition prior to the epidemic which occurred during the World War. The Committee on Nomenclature of the National Dental Association proposed the term Vincent's angina when the infection was in the throat and Vincent's infection when the tissues of the mouth were involved. The organisms are easily demonstrated in smears from the diseased areas.

Bercher contends that the lowering of the resistance of the buccal mucous membrane is the chief and primary cause, and that the organisms play a secondary rôle. He suggests that such reduction of resistance may be brought about by the following three causes.

1. A general infection, such as diabetes or scurvy, or by lead, phosphorus or mercury.
2. The infection accompanying the eruption of wisdom teeth.
3. A trophic disorder of the mucosa due to chronic alveodental irritation.

He lays great stress on the latter and seems to feel that this is the most frequent underlying factor, the removal of which is necessary before a cure can be effected.

SYMPTOMS

Painful inflammation along the margin of the gingival tissue, especially between the teeth. This

is characterized by sudden onset and by the formation of a grayish slough which sometimes extends rapidly and at other times slowly. The speed seems to depend on the previous condition of the mouth or the general health of the patient. The slough can sometimes be removed by a swab or sharp instrument exposing a red hemorrhagic surface. In the absence of treatment this quickly breaks down and forms another slough. The bloodvessels are early involved resulting in hemorrhages, spontaneous and induced, which sometimes occur during sleep. Such are thought to be of definite diagnostic value.

The breath has a characteristic foul odor.

Constant drooling of saliva in more severe cases.

Sleeplessness.

Loss of appetite. The soreness of the mouth renders it almost impossible for the patient to take solid food.

Fever is not common even in severe cases though the pulse rate may be considerably increased.

When the infection extends to the throat the general symptoms are much like those present when the gums only are involved, except that they are more severe.

Tonsils badly swollen and very red.

No exudate.

Sloughs and ulcerations especially involving the periphery of the tonsil. Ulcer may involve entire circumference of tonsil.

Tongue often covered with a thick fur which in appearance and thickness resembles moss.

Tongue very painful and tender.

Mental depression a common and distressing accompaniment.

Lymph glands involved. They sometimes become the most painful points of attack, especially when tonsils are involved.

OCCURRENCE

Neglected mouths most common.

Cigarette smokers seem very susceptible.

Syphilitics said to be very susceptible, but its occurrence in no way inplies the presence of lues.

TREATMENT

Dental.—Lightly remove all necrotic débris. Apply ten per cent. neosalvarsan in glycerine daily; or aqueous solution of iodine, followed immediately by twenty per cent. solution of silver nitrate. This causes a precipitate of silver iodide to form on the tissues and so eliminates the irritating action of each drug. This may be repeated at intervals of two days but should not be continued over a long period of time. Sodium perborate one teaspoonful in one half glass of either very hot or tepid water; writers are not agreed on the temperature of the water. My own preference is for very hot water as I believe the heat helps to relieve the pain. Perhaps the patient's preference might be consulted on this point. An original one pound package should be purchased and the mouth wash so made up should be used every half hour in severe cases; less often in milder ones. This wash should be continued for two months after the symptoms have subsided. Scale teeth superficially. Stop the use of a tooth brush. Postpone all operative measures until a cure has been effected. Light diet and rest. Other measures mentioned but not so highly recommended now as formerly: Peroxide of hydrogen locally. Permanganate of potash made up in solution the color of pink blotting paper for use in syringe. Hold syringe a foot or so from mouth and use considerable force in the injection. This serves two purposes: first, to wash away pus and other necrotic material, and second, to stimulate the gums. The organisms are killed by the oxygen from the permanganate. Silver nitrate in two per cent. to four per cent. solution applied locally. Copper sulphate in one half of one per cent. to one per cent. solution applied from atomizer. Loeffler's solution locally. Trichloracetic acid full strength. Tincture of iodine seldom used now except as described above. Tricresol five per cent. in alcohol. Zinc permanganate one grain to the ounce. Formalin. At the present time astringents are thought to have little value and escharotics are mentioned only to be condemned.

Medical.—Local: Paterson recently recommended the following formula:

liquor arsenicalis	2 drachms.
vin. ipecac	2 drachms.
glycerine	2 drachms.
aq. menth. pip to	1 ounce.

General: Potassium chlorate eighteen grains daily. Antimony and potassium tartrate one per cent. solution made up in sterile freshly distilled water and 0.5 c.c. of this solution injected intravenously. In two or three days a second injection may be given increasing the dose to ten c.c. Usually six injections will effect a cure. Great care should be taken to see that none of the solution is spilled in the subcutaneous tissues. Such an accident will cause great pain and probably incapacitate the patient for several days. Injections should be made very slowly to prevent nausea and vomiting. If this should occur the patient should be kept on the table for a few minutes when it will subside.

Occasionally a reaction resembling anaphylaxis is said to occur presenting the following symptoms; Redness of the conjunctivæ; suffusion of the face; swelling of the eyes and lips; dyspnea; acceleration of the pulse rate; cyanosis at times; symptoms of shock later. The treatment for this reaction is said to be 0.5 c.c. adrenalin chloride, one to one thousand solution hypodermically. Further treatment should be given carefully and probably with reduced dose. Neosalvarsan is mentioned in the literature but its value is not emphasized by most writers. Kritchewski and Seguin believe that the organisms can be killed by the use of arsenobenzol and the cure accomplished in that way. This coincides exactly with my own opinion.

Bercher holds a slightly different view and his outline of treatment follows. I believe that most men disagree with him when it comes to the operative measures.

"1. If the stomatitis appears during the course of a general disease (diabetes, scurvy) or an intoxication (lead, mercury, phosphorus), the treatment will be that of the general infection supplemented by buccal antisepsis which comprises filling and cleaning the teeth followed by applications of methylene blue, bichromate of potassium, etc., alternating with glycerinated neosalvarsan.

2. In stomatitis following infection of the coronary mucosa due to the noneruption of a wisdom

tooth, local arsenical treatment is unquestionably the best (with or without surgical intervention according to clinical indications).

3. When the stomatitis occurs, because the buccal mucosa has lost its resistance under the influence of a trophic disorder due to alveodental irritation, the destruction of the irritative lesion can only assure the cure. Arsenobenzol can only be an accessory agent. The discovery of the primary source of irritation can always be made, although difficulties may be encountered. The investigation must be pursued in and around the wisdom teeth because the source of irritation will most frequently be found there.

The following conclusion can now be formulated: All stomatitis which resists a well conducted local and general antiseptic treatment should arouse the suspicion of trophic disorder and cause a systematic and minute search to be made for the irritative lesion, the removal of the irritation will suffice to effect a cure."

PROGNOSIS

Usually favorable though it may terminate fatally. The patient may become so worn out by the loss of sleep and improper and insufficient food as to fall an easy prey to some intercurrent infection. The earlier treatment is begun and the more intensively it is carried on the better the prognosis. Relapses are more difficult to heal than the original lesion.

REPORT OF CASE

Case.—Mr. R., aged thirty-eight, was first seen for the present trouble on November 20, 1922. He said that he had had a sore mouth since October 20th. The day before consultation the trouble had extended to the tonsils and tongue. The extension caused enough pain and malaise to incapacitate him. The tonsils were red and swollen but not covered with any exudate. The sore mouth was confined to the right half of the upper jaw. The gums were covered, in places, with grayish slough. There was a line of inflammation along the margin of the gums on both surfaces. There were one or two ulcers on the mucosa of the cheek. The cervical lymph nodes were enlarged and tender. Smears showed large numbers of Vincent's organisms. The next day, November 21st, he was given neosalvarsan 0.3 gram; on November 22d and 23d each, he was given neosalvarsan 0.6 gram; the following day, November 24th, he considered himself cured and went to business.

On December 9th he came to the office saying that his mouth had been a little sore for a few days and the lesions around the gums looked about as they did when I first saw him. The tonsils were not involved. Smears again showed large numbers of Vincent's organisms. He was given neosalvarsan 0.6 gram on that day and on December 11th, 15th, 18th, and 20th, each, he was given 0.9 gram. His improvement was such that he again considered himself cured and discontinued treatment. From October 20th to November 20th he was under the care of a capable dentist, Dr. J. D. Johnston, whose treatment consisted of an antiseptic mouth wash, argyrol ten per cent. to the inflamed areas and of scaling of the teeth. From November 20th to December 27th Dr. Johnston did not see him.

During the period from December 9th to December 20th the ultraviolet ray was used on the throat and mouth. Applications were made every day or every second day. So far as could be determined this treatment exerted no favorable influence on the course of the disease. Looking back at it, I feel sure that more could have been accomplished by a different technic. I believe that this ray is a valuable agent in the treatment of this form of infection. I am told, but cannot verify it, that the ultraviolet ray has been used considerably in the Government hospitals in the treatment of this condition.

December 27th, I was called to the home and found the condition very much as I had seen it on November 20th. Neosalvarsan was again started; 0.9 gram was given December 27th, 30th and January 3d, 8th, 12th, 14th, 16th, and 18th. During this period he was also given neosalvarsan 0.9 gram in one ounce of glycerine for local application. The lesions did not respond to treatment and extended to the rest of the mouth and throat. His general condition became worse. Insomnia became very troublesome and the pain so severe as to require morphine. There was constant drooling of saliva and he was unable to eat much because of pain and difficulty in swallowing. Dr. Johnston went to the house twice a day to give local treatments. These, for a time, were neosalvarsan in glycerine, later peroxide of hydrogen followed by ten per cent. argyrol to the gums.

January 18th Dr. William Engelbach saw him in consultation. He agreed with the diagnosis but advised against the further use of arsenic fearing that a neuritis would develop and still further cripple the patient. January 19th, 22d and 23d he was given sodium iodide intravenously in doses of two grams. The condition remained unchanged or perhaps grew worse. He began to complain of numbness and itching of the palms and soles. Later these areas became covered with a red macular eruption, the lesions being about four by six mm. in size.

On January 24th it was decided to renew the neosalvarsan so 0.9 gram was given on that day. It was then suggested that arsphenamine might be more efficacious. On January 30th, 31st, February 2nd, 6th, and 8th he was given arsphenamine 0.6 gram. The only change was the production of a very painful and troublesome phlebitis in the right arm. From January 3rd to 18th he was given emetine hypodermically daily.

During all of this time the urine remained normal, neither albumin nor casts appearing. The blood also showed no sign of degeneration. His condition was growing a little more precarious. He could eat very little and could not sleep for any length of time. Morphine had to be given every night. The feet and hands were becoming more painful.

It was felt that since the arsenicals had been the only measure that had afforded relief perhaps the organisms had acquired a tolerance for the usual dose and that this might account for the lack of improvement during the last installment of the disease. The only sign of involvement of the nervous system was the condition of the hands and feet; so on February 12th it was decided to risk the production of a more severe neuritis and administer larger doses. On that morning he was given two tubes of 0.6

gram each of neoarsphenamine. These were given in twenty c.c. of water in a twenty c.c syringe. The result was almost magical. There was some improvement within four hours. Within twelve hours the pain had almost entirely disappeared. He slept well that night and ate a good breakfast the following morning. Within four days the lesions in the mouth had entirely healed. No more arsenic was ever given.

The condition of the palms and soles did not materially change. No treatment we could advise had any effect on this. He finally changed climate, going to a warmer one where hydrotherapy was given. This brought a very prompt change for the better. He has been back at work now for some time and is in pretty good health, although, at this date, August 11th, he still complains if he has to be on his feet for a great while.

The interesting features of this case were: The promptness with which neoarsphenamine effected an apparent cure early in the disease. Its complete failure to bring relief, later, when used over a long period of time in the ordinary dose. Finally, the very prompt subsidence of the disease following the administration of a single massive dose. My personal belief is that arsphenamine or neoarsphenamine is a specific for this condition. Given early and intensively it will cure practically every case. If the case does not respond to treatment the size of the dose should be increased. During the entire illness the doctor and dentist should work in conjunction.

The author's references will appear in his reprints.

Bronchial Asthma*

WILLIAM LINTZ, M.D.,
Brooklyn, N. Y.,
Clinical Professor of Medicine, Long Island College Hospital:

By the term asthma, I mean that condition produced by spasm of the involuntary muscles of the bronchioles, associated with swelling of its mucous membrane, with or without increased secretion of mucus, manifested mainly by expiratory and to a lesser degree by inspiratory dyspnea, which is intermittent and usually associated with paroxysms of coughing.

To my mind the term asthma (Greek for panting) is bad, for it is only a local manifestation of a general allergy, producing on account of its anatomical location a certain train of symptoms. The same allergic state manifests itself in other forms, such as rashes, particularly urticaria, angioneurotic edema, hay fever, mucous colitis, migraine, the digestive hemoclasis of Widal, etc. While it is true that these various manifestations of allergy give rise to entirely different trains of symptoms, it is equally true that arteriosclerosis gives rise to entirely different trains of symptoms, depending upon which tissue or organ is involved. The symptoms arising from arteriosclerosis of the abdominal viscera are entirely different from the symptoms arising from sclerosis of the cerebral bloodvessels. Yet we speak of general arteriosclerosis as the underlying disease. The symptoms arising from syphilis of the nose are entirely different from syphilis of the lung, yet we speak of syphilis as the underlying disease.

Patients with bronchial asthma frequently suffer also at the same time from the other forms of allergy mentioned above.

There is only one interpretation to such a condition, and that is, that the patient is suffering from the various phases of one disease and not a half a dozen diseases at the same time. This is illustrated by the following case.

CASE I.—A thirty year old woman complained that for many years, after eating certain foods, her face became swollen, but she had no difficulty in swallowing. Hives broke out all over the body, especially back of the knees, and this lasted from one to five days. At times she was nauseated and had an intense aversion for certain foods, especially eggs and sweets. Although as a rule she was constipated at times she had severe attacks of diarrhea. There was intense itching at the inner canthus of the eye, she caught cold continuously and had a running nose. Lately she had been having attacks of dyspnea and a dry spasmodic cough which lasted for an hour. These attacks came both summer and winter and were worse at night. She was nervous, irritable, and excited at times and suffered from severe frontal headache. Her menstruation formerly lasted five days, but now only two, and was very scanty. There was no relation between menstruation and the attacks described above. She was fifteen pounds overweight. Had areas of angioneurotic edema, especially over the face, and hives over the extremities; conjunctivitis, clogged nose, red hypertrophied tonsils, and slightly enlarged thyroid. Cutaneous allergic tests showed her very strongly positive to coffee, onion, beef, and meat, less so to chicken, cucumbers, and bananas, and slightly to grapefruit and cheese.

Diagnosis was as follows: 1. Allergy of the respiratory tract, producing attacks of hay fever and asthma. 2. Allergy of the gastrointestinal tract, giving rise to attacks of diarrhea. 3. Allergy of the skin, giving rise to urticaria and angioneurotic edema.

COMMENT.

Patient presented herself suffering at the same time from the various forms of allergy. Patients will present themselves one year with one form of allergy, say allergy of the skin, hives, itching, angioneurotic edema, and the next year they will present themselves with an entirely different form, as allergy of the respiratory tract—asthma. I believe that a

*Read in part, by invitation, before the New York Clinical Society.

more comprehensive nomenclature would be to call the underlying disease allergy and designate the different forms by the organs or tissue involved, such as allergy of the upper respiratory tract for hay fever, allergy of the respiratory tract for asthma, allergy of the skin, colon, etc.

The term anaphylaxis is quite frequently applied to bronchial asthma. The difference between anaphylaxis and allergy is that the latter occurs only in specially predisposed individuals, exhibiting particular hereditary traits, whereas anaphylaxis is a reaction common to all animal species and can always be provoked in any animal, including man, by parenteral injection of some protein. Furthermore, all attempts to produce a state of antianaphylaxis, which will last for any length of time, in animals previously sensitized, have so far failed, whereas we can obtain in over eighty per cent. of our specific asthma cases a period of desensitization lasting for some time.

The vegetative nervous system plays the leading rôle in bronchial asthma (1). An unstable (2) vegetative nervous system characterizes the asthmatic individual and makes bronchial asthma an inherited disease. While you must have some substance, either endogenous or exogenous which acts in a poisonous manner, in order to produce the clinical manifestations of asthma, we must remember that the contraction of the unstriped muscles of the bronchioles, the dilatation of the bloodvessels, which causes a swelling of its mucous membrane, and the increase of its thick secretion—the mechanism responsible for bronchial asthma can be produced only through the vegetative nervous system. An attack of asthma precludes an irritability of the vagus or a hypervagotonia. It is during the stage of hypervagotonia that the individual is especially susceptible to intoxication, producing the various allergic reactions. The intoxication then provoked is particularly prompt and severe, while during the stage of hypovagotonia or sympathicotonia the individual is relatively sensitive to intoxication and reaction to the very same substances. This represents the quiescent interval between the attacks. If attacks should be produced they are usually mild and delayed. The reasons why an asthmatic, after an attack, is free for a variable length of time from another attack of asthma, is because he becomes a hypovagotonic.

This conception explains the cyclic character or intermittency of bronchial asthma. It also explains why the very same substance can at one time produce a severe attack of asthma and at another time a very mild or even no attack; the intoxication depends upon the degree of hypervagotonia. It also explains not only why the patient who is susceptible to a given protein may at one time give a positive cutaneous test and at another time a negative test to the very same protein, but also why the cutaneous test may be very marked and prompt in its appearance at one time and at another time slight and delayed. It all depends upon whether the patient is at that time in a state of hypervagotonia, and if so, to what extent. It behooves us, therefore, in performing cutaneous allergic tests to make them shortly prior to or during an attack of asthma (3). The termination of an attack of asthma occurs as the hypervagotonic stage is gradually transferred to the hypovagotonic or the sympathicotonic. A sympathicotonic state terminates an attack of asthma promptly and definitely. This explains the usefulness of atropine in asthma, which, by paralyzing the vagal endings, produces a state of hypovagotonia. Adrenalin acts by stimulating the sympathetic and thus produces a state of sympathicotonia.

It is well known that the endocrines are closely related to the vegetative nervous system. In some cases of asthma the endocrines show definite involvement, and undoubtedly bear a close relationship to asthma.

Case I.—G. S., a six year old child, weighing forty-six and a half pounds, for the past three years had complained of choking, wheezing, dyspnea, and coughing, and at end of an attack would bring up thick yellow phlegm. These attacks came on once in three or four weeks, more often at night, lasted about three days, and were not influenced by season, climate, emanations and geographical location. She vomited after eating milk and eggs, which, however, did not always bring on an attack of asthma and were worse in cold weather. She also vomited during an attack and at the end of a coughing spell. Her nose was always clogged. Her father had coughing spells. She had had pneumonia and pertussis which lasted four months. She presented Hutchinson teeth, and no left central incisor. Had large axillary glands, wheezing, expiratory and inspiratory dyspnea and her lungs were full of all kinds of râles. A striking feature of the case was that the child presented a decided mustache over the upper lip. All laboratory examinations were negative. Cutaneous tests were positive only to egg white and egg yolk. A diagnosis of bronchial asthma was made, with endocrine disturbance—gonadopituotrope.

The child who had marked bronchial asthma, showed distinct endocrine disturbance—ovarian—as evidenced by the presence of a decided moustache. It is hard to tell definitely what relationship this bore to the asthma. It is significant that the child had pneumonia and pertussis which lasted for four months, establishing perhaps an infectious factor as a causal agent. While the child vomited after milk and eggs, the cutaneous tests were positive only to eggs. She did not always get an attack after eating eggs, and felt worse on cold days.

The manner of action of the endocrines, however, lies in the realm of theory and speculation. What we want is experimental proof in this direction and so far none has been forthcoming. If one will attempt to cure or even relieve asthma by endocrine therapy he will meet with disappointment. I state this as the result of actual trial in a large number of cases. Now and then, only, one meets an exception to this general rule as illustrated by the following case.

Case III.—B. C., a boy of twelve, weighing 125½ pounds, complained all last year of severe, more or less continuous, frontal headaches, and was nauseated and vomited frequently. He caught cold frequently and his nose was clogged. Had attacks of dyspnea, wheezing, tightness over chest, choking sensation,

and cough, and at the end of an attack would expectorate a viscid mucus. These attacks were not influenced by weather, season, location, time of night or day, food, or cold. He was sleepy most of the time and perspired a great deal. Tonsillectomy and adenoidectomy had been performed, and he had had operations on his nose from which turbinates had been removed. The mother and father both suffered from severe attacks of migraine.

The patient was a big boy, fifty pounds overweight, had a small head, left canine entirely different shaped from the right; he had flat feet but was otherwise negative.

X ray examination showed a small sella turcica, even when the small size of the head was taken into consideration, but no other evidence of pathology. One of the best nose specialists found an acute bilateral sphenoidal and left frontal sinusitis and insufficient drainage due to an old deformity of the nose which required more operations. All laboratory examinations, including the cutaneous allergic test, were negative. Diagnosis: 1, asthma; 2, migraine; 3, dyspituitarism; 4, sinusitis.

The boy was given at first two grains of pituitary extract three times a day, and then one grain, and the asthma, headache and nose condition cleared up entirely without operation. One year later the boy was free from all symptoms and had lost twenty pounds in weight. He was still taking one grain of pituitary extract three times a day.

As the boy improved promptly under pituitary extract, I believe it is safe to infer that the asthma was closely associated with the endocrines. It is interesting to note that with the disappearance of the asthma, all indications for nasal operations disappeared.

In certain female patients attacks of asthma are likely to occur around or during the menstrual period. This can be explained by the state of hypervagotonia, which exists at that time. Of course the hypervagotonia undoubtedly, at that time, does have an endocrine basis. One has a right to expect good results from the use of the endocrines in this group of cases, but so far the results have been exceedingly disappointing.

The intoxicating or allergic substance may be endogenous, or exogenous in character (4). Allergic substances of endogenous origin are usually bacterial in nature. These may come from the infections of the upper respiratory tract, rhinitis, sinusitis, pharyngitis, bronchitis, tonsillitis, abscessed teeth, unresolved pneumonia, infections of the genitourinary tract, and diseased appendix and gallbladder. In my experience, the rôle played by pulmonary tuberculosis in bronchial asthma is not more important than in other diseases. Yet I have seen asthma in both the incipient and the advanced stages of pulmonary tuberculosis. I have seen a good many cases in which the first attack of asthma dated from an attack following pandemic influenza.

In my experience with this infectious class of cases the mere removal of the focus of infection does not cure the asthma. In only a very few are the patients benefitted, and that for a very short time only. Sooner or later even in these few there will be a recurrence of the asthma. On the other hand, these patients are particularly benefitted if after the removal of infected foci, vaccine therapy is employed.

Rarely does an asthmatic of several years' standing enter the office but one or more operations have been done on nose and throat. I know of no anatomical portion of the body that is operated upon so much as the nose. But the limit of operations is reached when you come to consider the nose in asthmatics. All the theories about reflex neurosis and septic drainage and intoxication may be all right; but the results are not there. My warning to nose and throat specialists is to leave the nose and throat of asthmatics alone. An effort to cure true cases of bronchial asthma after any kind of operation on the nose and throat is sure to end in failure. If specialists will review their socalled cured asthma cases after operations, they will find that they have not been dealing with cases of bronchial asthma, but with other conditions producing clogging of the nose and dyspnea. Not every case of dyspnea is bronchial asthma. By this I do not mean to say that bronchial asthma is a contraindication for operation on the nose and throat. Not by any means. But do not make asthma an indication for operation. You will also be surprised to see how socalled normal indications for nose and throat operations will vanish when the patient is cured of asthma by other means. R. A. Gutmann reports (5) a group of cases of chronic appendicitis, in which pressure over McBurney's point invariably brought on an attack of asthma. He explained that this was brought about reflexly through the vegetative nervous system. He removed the appendix in these cases and cured the asthma.

Since writing this article I have been particular to exert pressure over McBurney's point in all asthmatics and have had no difficulty in eliciting pain and tenderness. This fact, together with the digestive disturbances from which all asthmatics suffer, would make a diagnosis of chronic appendicitis very easy, were I surgically inclined. However, I had the greatest difficulty, by pressing over McBurney's point, in provoking an attack of asthma. No patient has so far developed it. It is surprising to see how many asthmatics are operated upon for appendicitis. I believe that most of them are suffering from the intestinal form of allergy.

CONCLUSIONS

1. The term bronchial asthma should be substituted by the term allergy of the respiratory tract.
2. Patients will present themselves suffering from the various forms of allergy; such patients suffer from one disease and not from several diseases.
3. Allergy differs from anaphylaxis.
4. The vegetative nervous system is unstable in asthmatics.
5. Hypervagotonia plus the intoxicating substance is what precipitates an attack of asthma.
6. Cutaneous tests should preferably be made prior or during an attack of asthma.
7. Explanation of action of atropin and adrenalin which are useful in asthma.
8. Endocrines play an important rôle in asthma.

9. As a rule endocrine therapy is a failure.

10. Infections are exciting factors in some asthmatic attacks.

11. Autogenous vaccines are very useful.

12. Most of the operations on the nose and throat for the relief and cure of asthma are a failure. Cure the asthma by other means and the indication for operation vanishes.

13. In diagnosing appendicitis, care must be taken to rule out the gastrointestinal form of allergy.

What Is a Good Surgical Result from a Legal Point of View?*

CHARLES F. NASSAU, M.D.,

Philadelphia, Pa.

There may at times be an honest difference of opinion as to what constitutes a good operative result from a surgical point of view, and many additional features must be considered when the matter is discussed from a legal viewpoint. There is no fixed standard with which we may compare a particular result in order to settle the question. There is no one rule by which we may hope to arrive at a definite conclusion. Both discussion and recourse to the courts would be unnecessary if such a rule existed. It will be understood, therefore, that in selecting this question for consideration, I have no thought of being able to make any hard and fast ruling in the matter. It is obvious that I am incompetent to draw conclusions from a legal viewpoint, and I desire merely to point out a number of factors which must of necessity enter into each decision.

Strange as it may seem, the same legal standards in regard to surgical results do not obtain universally. In a number of instances, the courts have decided that a patient is entitled only to that grade of service which is standard in the community in which he and the doctor live. A patient living on a ranch, sixty miles from the nearest physician, cannot expect to have the same treatment that would be given in ordinary routine to any ward patient in a city hospital. The man living on the ranch might obtain as good a result as the man treated in the hospital, but this would not be so in all cases. For instance, the x ray is one of the surgeon's most valuable aids in the present day treatment of fractures. The patient on the ranch would be deprived of the benefit of x ray examination, without which he might have decreased function, malposition or both. Nevertheless I sometimes wonder whether we attach too much importance to it. It is quite possible that our skill and ability would develop to a much greater degree in the treatment of fractures by manipulation and dexterous splinting if we did not have the x rays for diagnosis or confirmation.

It is the surgeon's duty to give personal, painstaking and conscientious care to all fractures. Fractures were treated for many years before the discovery of x rays. They were very well treated, indeed, and, except in a small percentage of cases, the average fracture healed as well then as it does now. It has never been necessary for the surgeon to know that the bone fragments were in perfect apposition, or that the bone was just as straight as it had been before the break, in order to produce a good result. The surgeon of the days before the x rays knew that the point of fracture was not always in anatomical alignment, but he worked unceasingly to obtain function. That was the criterion. If a man had function, he had a satisfactory result. Anatomical accuracy, while desirable, has never been indispensable.

There is also a possibility that x ray examinations may lead to meddlesome surgery. A patient with fair contour and good function should not be subjected to the dangers that might follow an operation for the improvement of deformity. I remember very well an elderly man who had compound multiple fractures of both bones of the forearm. This man (at that time sixty years of age) had such a good functional result that he went back to his work as a beamer for one of the largest leather companies in Philadelphia. This happened in the early days of the x rays, so I had a skiagram made. The plate showed a dreadful "ram's horn" of bone which I would not have dared to exhibit to any patient, and without telling him a deliberate lie, I did everything that I could think of in order to prevent his seeing the plate, and finally destroyed it. Yet the contour of this man's arm was good, and function was perfect.

If I had believed that it was my duty to try to improve the alignment of the bones in this man's arm, and had operated upon him, it would be a good example of the meddlesome surgery that I mentioned previously. From a legal point of view, one look at the x ray plate would have convinced a litigiously minded attorney that the patient had been badly treated, in that he no longer had two straight bones. The attorney would have been mistaken in his opinion. Given function and fair contour, the anatomical picture of the bones is unimportant.

The fractures that most often lead to lawsuits are those of the femur, of the elbow, Pott's fracture, and that most common of all, Colles's fracture. A searching investigation in regard to the end results of fractures of the femur, made a number of years

*Read before the Medico-Legal Society of Philadelphia, January 30, 1923.

ago, with thousands of answers, was productive of the opinion that a shortening of not more than one inch was a good result and would be so decreed in court. Personally, I do not consider that a shortening of one inch in the average fractured femur constitutes a good result. I do not believe that a surgeon should be satisfied with any shortening that could be obviated by skillful treatment. The other extreme is illustrated by a friend of mine, whose fractured femur I was treating, who told me that he would not accept any result other than perfect end to end contact of his fracture.

There are certain fractures of the shaft of the femur in which we cannot obtain perfect alignment by any external method of manipulation known to surgery, even when the fracture is transverse. Perfect apposition of the fracture line in spiral fractures of the femur, by manipulation and extension alone, is, I believe, rarely possible. A fair proportion of fractured femurs, therefore, must be treated by some means of internal fixation. This introduces complicating conditions. In the first place, no man can operate upon any very large number of even simple fractures without having a death at some time—a death probably due directly to operation. I have never seen such an unfortunate occurrence, but I am willing to admit its possibility. Furthermore, internal fixation may be followed by nonunion, just as treatment by extension alone is followed occasionally by nonunion.

Various methods of treatment may produce vastly different results, and the cooperation of the patient is of enormous importance. If the patient were a definite factor, discussion would be without reason, but he always remains an unknown quantity. The most able surgeon, the most careful physician, may find his operation of negative value, his skill useless, because of a latent condition of disease in the patient and his failure to respond to treatment; or possibly he might act as one did recently for a friend of mine—get out of bed after an operation for the repair of fourteen perforations of the small bowel, eat some crackers, an apple, part of a banana, and then fill himself with water. This patient had an uneventful recovery, and perhaps bananas, apples, crackers and large quantities of water are the proper treatment for gunshot wounds of the intestine, although I doubt it. I believe that our legal friends would have held the surgeon blameless, had disaster overtaken the patient.

Treatment by different physicians may not be productive of the same result. Dr. X served an internship, engaged in general practice for several years, and then gradually specialized in surgery. He is, we will say, one of the surgeons to a hospital in a great city. Dr. X is marvellously skillful and operates with celerity and safety. If, perchance, he happens to cut the intestine, his demeanor is unchanged. The onlookers admire the skill with which he repairs the hole in the bowel and the operation proceeds. Is this man criticized? Not very much. Is he sued by the patient, even if it is discovered? Very seldom. Why? Because this man, with his training, his experience and his connections, would be able to go into the courts and practically set himself and his work as standard.

On the other hand, Dr. Y lives in a small town. A large general practice keeps him constantly engaged. He is one of a number of men who makes use of a local hospital which is open to all practitioners. Y has never had any special surgical training. He may never have been an intern in a hospital. It is true that he has been to Mecca, where he saw a large number of operations performed by a group of highly trained surgeons, with the result that he comes back to his community fired with a desire to do surgery. Another reason for this wish is that he may retain his hold on his own patients. Previously he has referred his surgical cases to his colleague, who is also in general practice, but who has had more surgical experience, and sometimes the patients have been retained. And so Y begins to operate. He is successful with the easy cases. He reads when he has time, and he reads somewhere a pernicious teaching—an operation reported by Dr. X. Y finds what he thinks is a similar condition and does that operation upon four patients, three of whom die. Dr. X does not do this operation in the type of case in which Y used it, but Y does not know this, and he is absolutely ignorant of the fact that his judgment was at fault.

If the relatives of these patients chose to sue Y for malpractice, he might not only have to pay damages, but he would also suffer a loss in standing and reputation, inasmuch as expert testimony would disclose the fact that an absolutely nonoperative procedure was the treatment indicated. Yet Y seldom suffers for his ignorance. His colleagues do not criticize him, because their own standards are not high, and they do not expect any wonderful exhibition of skill from their associate. Some men simply cannot realize their limitations. I shall never forget the occasion on which a friend of mine, no longer living, showed a child upon whom he had operated, and called attention to the splendid healing. Those present wisely nodded their acquiescence. As a matter of fact, every stitch hole was infected, and the wound itself had to be opened on the following day. It is impossible to tell whether or not this man realized his ignorance, but I do know that he made no further report concerning the child.

Nothing is ever gained by concealing disasters. It is only by a close and careful study of them, and of their underlying causes, that anything like perfection is achieved. Ignorance must be acknowledged before there is hope for improvement.

A proper understanding between the patient and the surgeon previous to operation places the surgeon in an unassailable position. It is not wise to be too optimistic. The patient may be told that he should be entirely relieved of his condition by operation, but he must understand that there is a certain amount of danger in any operative procedure. The possibility of a return of his malady should be discussed. As an illustration of this statement, authorities agree that in at least ten per cent. of patients operated upon for direct inguinal hernia a recurrence will develop.

The surgeon is, after all, merely human, more or less trained, and more or less skillful. Accidents occur even in the science of engineering, perfect as it is in the present day, axles and connecting rods break, starting gears go wrong and boilers blow up, and if machinery manifests these flaws, the human

economy is even more prone to do so, because of unsuspected pathology or errors in judgment.

If we had some standard by which a surgical result could be determined, the legal aspect would be plain. There is none at the present time, but the lines are being drawn more closely. The American College of Surgeons is beginning to judge of a man's fitness for surgery, and in a few years I believe that operations will be performed only by those men who have proved their ability before this association, and whose work is done in a manner satisfactory to it and for the patient's best good. It is true that operations of a minor type can and should be handled by a competent general practitioner, but such a man does not have sufficient leisure time to study and read as he should in order to keep abreast of current surgical progress. No man can be a universal specialist. It is impossible both to practice medicine well and do surgery as it should be done.

As you see, there is no one method by which a good surgical result from a legal point of view may be determined. A number of factors must enter into each decision. 1. Inasmuch as there is no one standard that we are compelled to attain, we must consider the standard that is in force in each patient's environment. 2. As long as we demand no special requirements of men who do surgery, we must consider whether or not they did the best work of which they were capable. 3. We must remember that patients vary, both in mental and body function, and while one patient may have a successful result, another may be either unimproved or may be unable to survive operation, owing to a complicating, heretofore latent malady, or the inability to withstand the shock to the nervous system.

There will be other points to consider in addition to those I have mentioned, for each individual patient will present his own problem. I believe, however, that the question has been discussed sufficiently. The thought that I wish to convey is that there is no one particular factor that is of supreme importance in making a legal decision on a surgical result. A broad outlook, an impartial mind and a tolerant attitude are the requisites for a just legal determination in each case.

Uncommon Commonsense in Medicine

BEVERLEY ROBINSON, M.D.,
New York.

Victor Hugo is responsible, I believe, for saying this in regard to many people and things in ordinary life. At least, so a friend writes me and his suggestion makes me apply it, in a small measure, to what I have seen in the practice of medicine.

The great value of commonsense in medicine is unquestionable and I shall try to illustrate it with a few examples. I have taken care of many patients of all sorts: rich, poor, ignorant, cultivated. The best, sanest patients were usually lawyers. As a rule, they selected their doctor with good judgment. Before selecting him they found out his experience, his standing with his peers, his character, his kindliness. Then, if ill, they confided in the physician selected, did as he advised, and when health returned were grateful in thought and deed for services rendered. They paid their bills promptly and often wrote an appreciative note with cheque enclosed. Business men, clergymen, women, frequently make a poor choice in their attending physician. They select him because friends say he is their doctor, or because he is young and, probably, with the latest and best knowledge, or simply because he has good manners and is attractive in person.

Again, many persons will take the newest drug with faith, when they would ignore, or throw aside, innocent and most reliable remedies, which have long been known and much used. Further, many patients will not take any medicine, or follow any timely, sound advice, unless the former is palatable and easy to take and the latter only when they are too ill to contest the matter. Further still, many people, even sensible men and women in other respects, make their own diagnosis of disease at first and take what they think best, or what an acquaintance, or the druggist counsels. At present, the rage is for the specialist, as soon as the disease is at all marked in any way, or because they think he knows more than the family physician. Hence it is that a doctor, or a surgeon, is no longer sufficient to take care of patients, but there must be an eye doctor, or a skin doctor, or someone who is a specialist for bones, teeth, throat, x ray, laboratory research, etc.

As to food and drink. The latter, thanks, perhaps, to Volstead, does now much less of the harm among well to do people. But they eat ill advisedly and far too much. Even when ill, they often want food that had much better be left alone. When the doctor tries to find out just what they do, he will often discover that they eat rich dishes with sauces, much sugar, and drink not a little tea and coffee. Of course, they often finally ruin their stomachs and teeth. When advised against much of all this bad doing, they simply answer they always have done it and many others do it.

I might go on in this way for many pages but I prefer to stop with a few additional remarks. If people, usually, would only use their commonsense in medicine, as they do about their money, there would be far less illness, and precautions of a rational kind to guard precious health would be followed. It is relatively simple to avoid disease; it is very difficult to regain health when once it is lost. And when long habits of bad living in a health way have been followed, it takes much time and some sacrifices to regain it, and that blessed result can come only in this way. If the physician were selected, as wise men and women should select him, the world would be far happier and healthier.

125 East Thirty-fifth Street.

Sinusitis*

FRANCIS W. WHITE, M.D.,
New York

The term may seem somewhat ambiguous but the condition is becoming so prevalent that one immediately thinks of an inflammatory affection of one or more of the nasal accessory sinuses without further determinative. These sinuses normally contain air and some secretion from the mucous membrane lining, in contradistinction to the lateral or sigmoid sinus normally blood filled, or the surgical sinus, a fistulous tract. The lining of the nasal accessory sinuses is continuous and practically the same in structure as that found in the nasal chambers, with the exception of the membrane in the antrum of Highmore, or maxillary sinus, which is ciliated. It is evident then that the lining membrane of the accessory sinuses is subject to the same diseases as the mucosa of the nose, as there is normally an interchange of air between the nasal cavities and the sinuses. It must also be borne in mind that secretions from the sinuses pass into the nasal chambers, and that under certain circumstances the reverse occurs. The accessory sinuses, however, are much better germinating places than the nasal chambers, as they offer the four most important factors for microbic growth, namely, heat, moisture, darkness and medium. Aside from trauma, neoplasms of the sinuses, the specific infections, and uncommon inflammatory conditions of the nasal mucosa, the almost daily treatment of intranasal diseases by the general practitioner is more particularly concerned with the catarrhal or suppurative forms of sinusitis.

The stages of inflammation in the lining membrane of an accessory sinus are the same as in a mucous membrane anywhere else in the human body. The simple acute catarrhal form may pass away without leaving any appreciable traces, but repeated attacks will sooner or later lead to the chronic form in which there is, first, a persistent swollen condition of the membrane, sometimes termed hypertrophy, to be followed by the formation of fibrous tissue and an ensuing shrinkage or atrophy. The acute suppurative form may arise as such and be cured, but leave a certain amount of pathological change to be followed by other acute attacks, or slowly pass into the chronic suppurative form with positive changes in the membrane.

The acute catarrhal form of sinusitis is the most common and the type most frequently overlooked, for the reason that the average individual makes his own diagnosis of a "cold in the head," and after a varying period of selftreatment he seeks medical advice. The inflammation is now undoubtedly in its terminal stage and responds quickly to treatment. With the onset of the next attack selftreatment is again instituted as before, except that the medical treatment outlined previously for the terminal stage is now used in the first or second stages. This is manifestly not only illogical, but is decidedly detrimental, in that it prolongs the stages preceding the terminal stage which is also prolonged unnecessarily. This series of events often repeated leads into the more intractable chronic catarrhal state, if perchance it does not suddenly go into the acute suppurative form of inflammation. Therefore, when called upon to treat the condition termed a cold in the head, a searching examination should first be made to determine if one is dealing with a simple ordinary rhinitis, or an acute catarrhal sinusitis.

The history is important. If the patient is interrogated regarding the amount of discharge from the nose during a day, the answer will usually be that a large number of handkerchiefs are required or that it is almost impossible to eliminate the constant use of a handkerchief. The statement that it is almost impossible to be free from a cold; that about as soon as one cold is cleared up another supervenes, is also significant. These statements are two of the most important diagnostic criteria. Treatment should not be instituted at this time, but a rhinological examination as complete as possible should be made, and if, as is surmised, the membranes are swollen and bathed in secretion, an astringent solution, such as one of the suprarenal extracts, should be applied either by means of the atomizer or pledgets of cotton applied locally. It may require several applications to shrink the membranes thoroughly and they should be shrunken throughout the entire length of both meatus anteroposteriorly, when this has been accomplished, a warm mild alkaline douche should be employed to remove all the secretion contained in the nasal chambers. Great care must be exercised not to use undue force or pressure to accomplish this for fear of forcing the infected material into other cavities or spaces. This is most important. After having thoroughly cleansed the nasal chambers, the patient is allowed to remain quietly in the sitting position for a few minutes, the head being tilted slightly forward and downward.

Upon reinspection of the nasal fossæ, if a simple acute rhinitis is present no appreciable amount of discharge should be discernible, but if the catarrhal form of sinusitis is present a streak of discharge, either serous or mucoid in character, will be seen on one or both lateral walls, particularly in the region of the anterior tip of the middle turbinate. If this discharge is gently swabbed away, more discharge will shortly reappear in the same location. This indicates an involvement of one or more sinuses of the anterior series. Discharge appearing and reappearing in the neighborhood of the posterior tips of the middle and inferior turbinates would be associated with sinuses of the posterior series. In cases of acute or chronic suppuration, the detection of discharge is rendered easier by the whitish or creamy appearance of the pus.

Strange as it may seem, inspection of the throat is important, for there will be found striking evidence of sinus involvement. In many patients suffering from sinusitis there is to be found intranasally some irregularity or actual deviation of the nasal septum which precludes the proper drainage

*Read before the Medical Board of the Peekskill Hospital, Peekskill, N. Y.

and ventilation of the nasal fossæ. These irregularities and septal deflections plus the turgescent condition of the turbinates prevent the free flow of discharges anteriorly, and as a means of escape they must of necessity to some extent flow posteriorly. The presence of a mucoid or purulent discharge upon the posterior pharyngeal wall, especially when appearing as if escaping from behind the soft palate while the patient is saying A, is almost pathognomonic of sinus involvement. When this discharge reaches the laryngopharynx the patient will often be annoyed by the necessity of clearing the throat and at times by being forced to displace the discharge by means of a short decisive throat cough. At times it may be necessary to repeat this procedure two or three times before the voice becomes clear. At times the quantity of discharge is such that it must be expectorated. If the discharge is not gotten rid of in this manner it is possible for a certain amount to pass into the trachea and possibly the bronchi. Most of it, however, passes by means of the esophagus through voluntary and involuntary deglutition into the stomach, which in time responds unfavorably, as do also the intestines, causing numerous gastrointestinal symptoms, of which excessive gas formation is one. It is my opinion that the various forms of nasal accessory sinusitis will in the near future be given a prominent place in the list of etiological factors in the causation of acute and chronic gastrointestinal medical and surgical conditions.

It is the exception for children to expectorate accumulated secretions in the pharynx or properly blow the nose for clearing purposes, consequently sinusitis is a particularly vicious condition for them as practically all of the discharge passing from the nose into the pharynx is swallowed. A child with a running nose and gastrointestinal disturbances is frequently encountered, and the younger they are the more difficult is the feeding problem. Fortunately, the adenoids in such children are removed at an early age, thus removing one of the mechanical causes of sinusitis. No doubt many of us have not been perfectly satisfied with the results obtained by an adenoidectomy, one of the most disappointing being the lack of improvement in nasal breathing and lessening of the nasal discharge. The cause for this may be an infrequent condition, namely, atresia of one or both choanæ, but more frequently it is due to some maldevelopmental condition, as an irregular intermaxillary ridge or deviation of the nasal septum. Therefore, before advising adenoid and tonsil removal for the relief of faulty nasal breathing and excessive nasal discharge, insist upon a thorough intranasal examination. I wish to lay stress upon one point, however, and that is the possibility of a low grade diphtheritic infection of the nose in children. This should always be borne in mind as it may be more common than is realized.

It is not the purpose of this paper to go into a detailed description of the signs and symptoms of sinusitis, but rather to point out a few of the more easily confused features and to call your attention to the possibility of an underlying sinusitis as an obscure cause for some of the cases in general practice that do not respond to treatment as would be expected. Naturally one of the symptoms complained of is headache. This is far from being characteristic of sinusitis. In fact, many patients will state they are suffering from sinusitis associating headache with the ailment. Even with pus in the nasal fossa it is not of necessity an associated symptom. There is one peculiarity of a sinus headache, that is at times quite prominent, namely, periodicity. A patient may state that the headache occurs regularly at the same hour each day. It may be in the morning or it may be in the afternoon, but the fact that it is periodical is impressive to the sufferer. It may be the result of posture either while asleep or while at work. It lasts a fairly definite length of time and then disappears, leaving in its stead a sensation of soreness in the area involved. Complaint may be made of a sensation of fullness as if a part of the head or face were about to drop out, or of a bursting sensation of the part covering an inflamed sinus when the patient bends the head downward. There are two main causes for a sinus headache—excessive pressure within the sinus due to insufficient drainage and in chronic suppurative cases bone and nerve involvement, particularly when the sphenoid sinuses are involved. As stated before, many patients suffering from sinusitis have irregular or deviated nasal septa. As it is impossible for a sinusitis to exist any length of time without rhinitis of the same side either primarily or secondarily, headache would naturally be present, due to the pressure associated with the swollen structures in the nose pressing upon the sharp points of irregularity of the septum or its sharp or bowing deviation. A common and frequently overlooked cause of headache simulating sinus headache, especially of one or both anterior series of sinuses, is a myositis of one or both sternocleidomastoid and trapezius muscles. The temporal muscle and muscles in the supraorbital area may also be involved or may be dragged upon by the tense sternocleido and trapezius muscles. This may cause a headache or at least a pain in the frontal region. If pressure is exerted over the supraorbital area pain is elicited, due to involvement of the supraorbital nerve and consequently be misleading regarding a sinusitis.

Tenderness upon pressure over an involved sinus is not characteristic of sinusitis as the causative factor, as, for example, exposure to cold may also cause an inflammation of a nerve or nerves. This is particularly true of the trifacial nerve. The teeth should be carefully examined and the alveolar processes of the upper jaw carefully inspected and palpated, especially in the region of the first and second molars, bearing in mind the proximity of the roots of these teeth to the floor of the antrum. The canine fossa may be an area of tenderness due to the involvement of the root of the tooth of the same name and thinness of the bone covering it anteriorly, thus simulating antral disease. The excessive tenderness elicited at the inner angle of the orbit may be due to frontal or ethmoid disease, or both. To distinguish between frontal and ethmoid involvement, for the former pressure is made upward and outward and for the latter inward and downward, both motions being of a rotatory nature, or at least following the contour of the bone in the directions noted. Manifestly in frontal disease in which there is erosion of bone pain or tenderness can be elicited

directly over the front of the sinus with no chance of mistaking it for a supraorbital nerve inflammation.

Eye symptoms are not uncommon—blurred vision, sudden loss of vision, and pain behind the eyeball should be danger signals calling for a complete vision and eyeground examination followed by a complete rhinological examination. Such conditions as optic neuritis, thrombosis of the central vein of the retina, papillitis and double chocked disc may arise in the course of sinusitis. Unfortunately these are at times of insidious onset with but scanty discharge from the nose. Even upon opening up the ethmoids and sphenoids radically often times only a small quantity of a watery somewhat milky colored fluid is released. Not infrequently the opthalmologist by a process of exclusion will ask to have something of a radical nature done to the sinuses as a last resort in the hope of affording relief or as a means of cure. Under such circumstances laboratory collaboration, namely, uranalyses and the Wassermann reaction, is imperative. The use of the x ray is highly important, not only from the diagnostic but more particularly from the surgical viewpoint.

To illustrate, reference is here made to two instances of recent occurrence wherein there was no doubt as to the presence of an acute suppurative frontal sinusitis. All the classical signs were present over both frontals in each patient, but in each instance one side showed more marked evidences than the other. Operation was imperative, but following the dictum "no x ray, no operation" (this cannot be stated as being irrevocable—there are circumstances negating it), much unnecessary exploration and time were saved by the reading of the still wet x ray plates. These showed not a bilateral suppurative frontal sinusitis, but a marked deviation from the anatomical normal. The septum between the two frontal sinuses was in each patient far to one side of the median line of the body. The diagnosis then was not bilateral suppurative sinusitis, but unilateral—one large sinus showing severe involvement and one small sinus showing mild involvement. The larger sinus only, in each instance, was opened and the subsequent course of events proved the great value of the x ray in showing anatomical variations and thus expediting surgical procedure.

X raying of the teeth should be done at frequent intervals, however, irrespective of any sign or symptom referable to a sinusitis. A crowned tooth should always be looked upon as a potential focus of infection.

Transillumination is of doubtful value except in marked differences of the maxillary antra, and if this is great the symptoms would have already directed attention to this sinus.

Eustachian tube and middle ear involvement is frequently secondary to the rhinopharyngeal inflammation arising in the course of a chronic sinusitis. It is not necessarily a direct continuation of the inflammatory process but secondary to lymphatic absorption and transmission. Manifestly an acute suppurative otitis media may be induced mechanically by the transference of infected sinus discharge into the eustachian tube as in outdoor or tank bathing or by means of the excessive air pressure used to clear an obstructed nose of mucus or pus.

Anosmia or loss of the sense of smell is a symptom not infrequently complained of, and at times its sudden onset is the chief reason for the patient presenting himself or herself for treatment. Their greatest concern is regarding the permanency of this ailment. Anosmia associated with an acute catarrhal sinusitis or rhinitis invariably disappears with the retrogression of the inflammatory process and consequent lessening of the swelling of the involved intranasal structures. Parosmia or perverted sense of smell is not so frequent, but at times patients complain of everything seeming to have the odor of burned straw or other substances. This condition rarely persists, but in the event of either being present and the sufferer seeks advice upon the matter, attention should immediately be directed to a sinusitis being the cause and a differentiation made between pressure and actual nerve disease, or a psychic state of the patient.

RHEUMATISM

Any person who has passed through life without having suffered from rheumatism in one form or another to some degree must have been born, lived and died in the ethereal state; in other words, rheumatism is the most common and widely disseminated condition known to affect living creatures. It is selfevident, then, that its remote causes are manifold, but its specific cause with very few exceptions undoubtedly is a toxin. In any case of rheumatism it is incumbent upon the physician to institute a diligent search for a focus of infection and not to be satisfied with the locating of one, but when possible eliminate it, and be on the lookout for still another. If you consider for a moment the location of a nasal accessory sinus and its possibilities for harboring infective organisms, the chances of being the seat of an active or low grade inflammation and the possibilities for toxin absorption, you can readily appreciate its potential possibilities as an underlying or even accessory cause of rheumatism. Unless the lining membrane has become thickened absorption is rapid. The more permeable the membrane the more prone are certain symptoms to arise, provided a toxin is present that is inimical to that particular person. As the natural opening to any of the sinuses is comparatively small, mostly poorly situated for drainage, and the mucous membrane surrounding it somewhat loosely attached, any inflammatory process increases the bulk of the membrane and consequently decreases the size of the opening. A thin infective retained secretion is more likely to be absorbed and therefore cause symptoms of a systemic character. If there is not marked retention and a small quantity of discharge escapes, and due to caues inherent in the nasal formation passes into the pharynx there is a vast area of lymphoid tissue being bathed in a discharge of varying toxicity. That absorption does occur from lymphoid tissue requires no further proof than citing acute tonsillitis as an example, for such an acute lymphoid inflammatory reaction with the concomitant systemic symptoms is selfevident. It is in the mild types that the most frequent irreparable damage is done, in what might appropriately be termed the ambulatory forms of intermittent or chronic lymphoid involvement, for while reference is

here made to the tonsils, it must not be forgotten that the pharynx is practically surrounded by a ring of lymphoid tissue, including the adenoid and the lingual tonsillar tissue. With this ring intact in a child suffering from so-called growing pains, give the little patient as much consideration as if decidedly ill, and seek for a focus of infection from above downward, for no doubt the presence of endocarditis discovered in later childhood or early youth is the result of forcing the little sufferer to keep pace with more fortunate playmates. Reference is again made at this point to the baneful effects of infected discharges passing into the gastrointestinal tract, with a perversion of its normal functions and a consequent toxemia expressed in the form of joint, muscle or nerve derangement.

Asthma like rheumatism is a condition arising from many causes and most frequently requires much thought and great patience to discover the cause. When successful, it is usually by means of the exclusion process. It is not within the scope of this paper to intimate the various causes of asthma nor to outline the treatment thereof. It must suffice to mention sinusitis as one actual or underlying cause and to direct attention to this fact. Cures have been obtained by the elimination of a focus of infection, particularly the ethmoid labyrinth and especially when affected by the hyperplastic form of inflammation. The infected antrum has also been a not infrequent cause.

Laryngitis of the subacute and chronic forms are often associated with sinusitis and no treatment directed to the amelioration of them is of benefit. This can only be corrected by clearing up the sinus infection and the consequent ceasing of the naso-pharyngeal discharge. This being so, it is highly important to remember this association and when called upon to treat a patient giving the history of intermittent or continuous laryngeal affection, be certain of the absence of a sinusitis before making applications to the larynx or instituting any other form of treatment.

SUMMARY

To recapitulate, the most important points in the history of the patient are the complaints of incessant discharge from the nose and frequency of the attacks of head colds during inclement weather.

Headache to be differentiated from that caused by sinus, muscle, and nerve involvement.

Eye symptoms, such as slow or sudden loss or blurring of the vision.

Rheumatoid and asthmatic conditions.

Less frequently, variations in the sense of smell.

Singly or in combination the conditions mentioned above indicate as complete a rhinoscopy as possible, and an examination of the pharynx for discharge coming from above.

Laboratory methods to be used in all eye cases giving these symptoms.

The use of the x ray and transillumination as adjuncts.

174 WEST FIFTY-EIGHTH STREET.

Prolapse of the Ventricle of Morgagni

PROFESSOR SABRAZES and ANDRE LUSSAN
Bordeaux, France
Faculty of Medicine of Bordeaux

Before considering the subject of prolapse of the ventricle of Morgagni, we would first study briefly the anatomy of the laryngeal cavities, with special reference to their diverticula. Fränkel, of Berlin, some time ago published an important study of his subject and our researches have verified most of his histological findings, while we have cleared up certain points that the Berlin observer left uncertain.

Morgagni, in his *Inadversaria Anatomica,* says: "Between the two thyroarytenoid ligaments a slit almost elliptical in shape is found on each side, large enough to insert the end of the thumb or finger, according to the size of the larynx. These slips are openings of remarkable cavities. The lower part of the thyroarytenoid is situated underneath their lower wall. Outwardly, they are covered for quite an extent by the middle and upper fibres of this muscle. At the point where they approach the epiglottis, these cavities are more or less high, because there is a diverticulum or appendix present, easy to feel with the probe."

This diverticulum, situated in front at the point where the ventricles approach the epiglottis, is usually regarded by most anatomists as homologous to the large cavities present in certain mammalia and known by the name of laryngeal sacs and extend more or less far down into the region of the neck or thorax. Thus in the orang-outang these diverticula, filled with air, are seen to cover the anterior aspect of the neck or even to descend into the axillæ. Functionally they are regarded as true sounding-boards.

The ventricular cavity is elongated in the antero-posterior direction, while its transversal diameter is directed from within outwardly. The diverticular appendix forms with this cavity a right angle bend whose bisector is situated from above downwards and in front backwards. It dilates above and behind. It passes out through an orifice hardly larger than one millimetre by narrowing itself on the upper wall of the ventricle. This orifice, whose starting point is in the ventricle, just beside the epiglottis, terminates, according to Fränkel, behind near the middle third of the upper wall of the ventricle, the corresponding half of the larynx being looked at full faced.

What is the shape of the appendix? Morgagni, Luschka and other observers simply measured its length by means of a probe, but this procedure gives very indefinite results, because the appendix, sur-

FIG. 2.—Suspensory ligament of the laryngeal mucosa at the ventricular bands.

rounded as it is by soft structures, allows itself to be lengthened or pushed aside. The same objection can be made to the procedure of moulding generally employed. In this respect Fränkel made a long series of sections and he came to the conclusion that the dimensions and shape of the appendix vary considerably from one subject to another. Thus the upper dome which usually extends to the arytenoepiglottic fold varies in height, not only in different subjects, but in the same subject if both sides of the larynx are examined.

We shall give a detailed description of the sections we have made at the level of the region of the larynx under consideration with an attempt to bring into relief those details not touched upon by Fränkel, such, for example, as the considerable abundance of the closed follicles adjacent to the diverticula and the arrangement of the fibroelastic tissue. We also give drawings of horizontal sections that we made on the normal larynx of a four and a half year old child who died of tuberculous meningitis.

This larynx, obtained thirty-six hours postmortem, was nevertheless in a very good state of preservation because the weather had been very cold. It was fixed in Kleinenberg's fluid, then washed in running water before being included in paraffin. We have obtained excellent results by leaving the sections, previously glued on glass slides with thirty-three per cent. alcohol and deparaffinized, for about an hour in water before treating them with picric thionin (Sabrazès), which makes their preparations very favorable for a minute study of the section.

The transverse sections, passing at the limit of the ventricular bands and arytenoepiglottic folds, above the ventricle of Morgagni, offer a rounded surface, having for centre the laryngeal cavity which has a grossly lozenze shaped outline with a great antero-posterior diameter. The posterior angle is flanked on each side by the two arytenoid cartilages which form two oval zones.

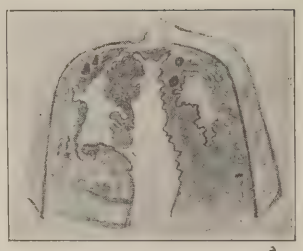

FIG. 3.—X shows point of entrance of the diverticulum above Morgagni's ventricle.

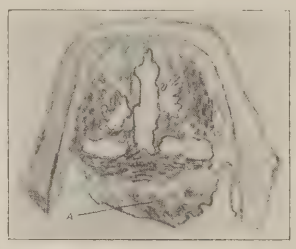

FIG. 4.—A, pharyngeal glands.

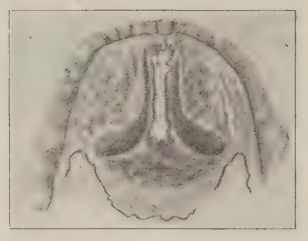

FIG. 5.—Transverse section of larynx at the level of the vocal cords. X shows the anterior group of glands.

The anterior angle has the appendices of the ventricle of Morgagni on each side, in their ensemble lying parallel with the sides of this angle from which they are separated for a distance of one and a half to two millimetres. In front the sections are bounded by the thyroid cartilage. The mucosa which lines the central cavity of the larynx is tortuous. It consists of stratifications of cylinder cells measuring from about 46.5 micron to 93 micron in thickness. The superficial layer is composed of cylinder cells with cilia, these being detected with difficulty. Some caliciform cells are interposed and here and there are gorged with mucus, the thionin resulting in a violet metachromasia. The free edge of this epithelial lining is dotted with cellular débris, desquamated epithelial cells, and a few polynuclear leucocytes. A few leucocytes with a polymorphous nucleus are also to be found in the midst of the deep seated epithelial cells; they are readily recognized by the aspect of their nuclei and the intense stain taken on by the latter. Among the lining epithelial cells which contain a distinctly outlined oval nucleus in which chromatin is condensed in one or two small nucleoli, there are some whose nucleus is deprived of nuclear membrane and transformed into a chromatic mass. Others are seen in a more advanced phase of division.

The subepithelial stratum is implanted on a membrane forming a plasmic line 3.48 micron broad. The chorion is formed by interlaced thin fibred connective tissue which is traversed by numerous fixed cells and is arranged parallel to the laryngeal cavity surrounding it like a ring. These connective tissue fasciculi are made evident by acid picric fuchsin. Many capillaries are to be seen 15.5 micron distant from the basal membrane. Occasionally they are only 46.5 micron to 62 micron distant from each other and are gorged with red blood corpuscles.

Not far from the basal membrane one also finds the excretory ducts of the glands in longitudinal or transversal section, in the latter case measuring about 31 micron. They are regularly round, bordered by a single layer of cylindrical cells, while their central lumen, containing mucus, measures hardly more than 15.5 micron.

In the chorion, 66.2 micron from the basal membrane, follicles exist whose broadest diameter varies between one half to one quarter of a millimetre. One of these follicles is to be found especially on one of the sides of the $\wedge$ formed by the laryngeal mucosa, traversed by two glandular excretory ducts and presenting a gaping capillary on the edge facing the basal membrane. The apex of the $\wedge$ joined in front by the cavity of the larynx is lined with an adenoid tissue lying immediately under the epithelium, but this arrangement is not depicted in our drawings.

In the chorion one also sees in its midst acinous

glands, some of which empty directly into the laryngeal cavity, the others into the diverticulum prolongations of the ventricles. The largest of the glandular lobules measure 662.8 micron, the smallest 331.4 micron. Their excretory ducts are not situated in the centre but on the side of the glands. The oval acini, in close juxtaposition, are made up of a basal membrane lined with parietal cells; their central lumen is filled with nuclei derived from desquamated cells. The epithelium of the excretory ducts is cylindrical and distinctly outlined. These glands are very numerous, there being some thirty lobules on each side between the diverticulum and the laryngeal mucosa.

THE DIVERTICULA

The distance separating the laryngeal mucosa from the diverticulum is, in front, 165.7 micron; but this distance varies from 828.50 micron to two millimetres. The diverticula are symmetrically arranged in the sections we are envisaging and measure two millimetres in length and 1.15 mm. transversally. They present very irregular contours, their lumen being filled with desquamated epithelial cells. They are lined with very long cylindrical cells with cilia, visible only at certain spots of the mucosa, but absolutely unmistakable. Among these cells some are to be found ending in a plateau, others assume the aspect of caliciform cells. These cells, with an elongated nucleus, form a very dense line; they are thin, arranged in one or two layers irregularly distributed, and, so to speak, dovetail each other. The total height of this lining is about 994.20 micron.

At this level (Fig. 1) the diverticula present two follicles immediately under the mucosa, one in front, the other behind and inwards. There is also one on the internal side and two on the external side. Besides, there is a very large follicle situated in the midst of the chorian between the diverticulum and the thyroid cartilage, 257 micron behind this cartilage and 330 micron distant from the diverticulum. The lymphoid clusters are united with each other by adenoid tissue which borders practically the entire diverticulum. These follicles are traversed by gaping capillaries. Excretory gland ducts are also to be found in the very substance of the follicles. These ducts empty into the cavity of the diverticulum and in serial sections the point of anastomosis of these excretory ducts can be distinctly seen.

Quite numerous vessels twine about all the follicles, their calibre measuring from 400 to 414 micron. All these structures are buried in a thin fibred fasciculated connective tissue which becomes thicker around the vessels.

Besides the follicles there are also numerous glandular lobules, particularly near the diverticula and around which the connective tissue is more abundant. Striated muscular fibres lie between the laryngeal mucosa and the apex of the diverticulum and are especially numerous in front of it. In the midst of these fibres glandular lobules are embedded and assume very close relationship to the thyroid cartilage, although without penetrating it. Some of these lobules are even in contact with the perichondrium. Behind, these glandular islands likewise come very near to the arytenoids and acini can be found 66.28 micron distant from the cartilage.

This description applies equally to both sides. There are two diverticula presenting the same anatomical arrangements, but the grouping of the follicles around them is not absolutely symmetrical.

Glands are found behind the arytenoids where a dozen lobules empty into the laryngeal cavity by a single common duct. The laryngeal cavity is incomparably less rich in adenoid tissue than the cavity of the diverticuli. The cartilage belongs to the hyaline type.

In these same serial sections we have studied the topography of the elastic tissue with orceine acid (Fig. 2). The entire region lying behind the arytenoids is extremely rich in elastic tissue; the fibres entwine the glands and fasciculi extend parallel to the mucosa from 82.85 micron to 99.42 micron distant from it. These fasciculi become thicker behind the thyroid where on each side are four fasciculi measuring from 99.42 micron to 165.7 micron in thickness. The perichondrium continues without any line of demarcation with the fibroelastic tissue. At this spot the chorion is solidly united to the perichondrium by fine fibred connective tissue heaped up against each other and which dip into the thyroid cartilage like a wedge, becoming intimately mingled with the perichondrium. This arrangement forms a veritable suspensory apparatus for the mucosa, with an elastic framework, a common centre at which the lower ligament of the epiglottis and elastic fasciculi end, encircling the laryngeal cavity like a ring. On the other hand, the elastic tissue surrounding the diverticuli is reduced to a few fibrils around and in the follicles. Around the glands and in the muscular areas there is a rather marked development of the elastic tissue.

In the sections made in the lower region of the ventricular bands (Fig. 3) the thyroid cartilage lies in front and the arytenoid cartilages behind, forming an oval surface. The epithelial lining is of the stratified pavement type and around the epithelial border mucous glands exist, some of which empty directly into the cavity of the larynx. At the level of the mucosa belonging to the bands is to be found a single lymphoid mass, and this poverty of adenoid tissue contrasts with the rich development of follicles in the walls of the diverticula which contain four or five large follicles connected with each other by submucous adenoid tissue.

The diverticula have an extraordinarily clear outline and in serial sections we fell exactly upon the isthmus of communication (measuring 160 micron) of the appendix with the laryngeal cavity (Fig. 4). At this lever there is an extraordinary abundance of glands. Thus on each side, between the arytenoids and the ventricle, exist nine clusters of glands and seven or eight others between the diverticulum and thyroid cartilage. These glands, both at the level of the thyroid and arytenoid cartilages, are in direct contact with the perichondrium and are embedded in fibrous tissue whose structure recalls that of the perichondrium. The vessels are here more numerous than higher up and outside the arytenoids there are two or three thickwalled arteriolæ.

The muscular tissue is arranged in fasciculi to the outer side of and behind the ventricle, in front and to the outer side of the arytenoids, and at this level it continues with the perichondrium by means of

minute tendons. Some of these tendinous fasciculi extend along the side of the thyroid cartilage.

Other serial sections involve the lower portion of the ventricles showing the pharyngeal mucosa composed of stratified pavement epithelium (Fig. 4). This region is convex behind in its middle and the mucosa afterwards folds upon the wings of the thyroid cartilage, assuming the shape of a capital M, the middle downstroke of the letter being rounded (Fig. 4).

Below the pharyngeal pavement epithelium is loose connective tissue containing a few excretory ducts of glands. In the middle portion, corresponding to the down stroke of the M, these ducts are four in number. At this spot numerous pharyngeal glands exist forming thirteen lobules around which the connective tissue is thickened. The glands are accumulated at the tip of the M to the extent of 2.716 mm. In front of them is a muscle arranged in the shape of a transverse sling between the laryngeal and pharyngeal cavities. Laterally the pharynx forms two lateral excavations whose chorion is made up of loose fibrillary connective tissue transversed by vessels and nerves.

The laryngeal cavity has a grossly pisiform aspect, the posterior part being bifid and the median portion raised, while the anterior end tapers off. It is entirely covered by stratified pavement epithelium and on each side the ventricular cavities are completely isolated from the laryngeal cavity by a narrow bridge of tissue and lined with stratified pavement epithelium.

The arytenoid cartilages are very near the mucosa and slightly inflected from behind toward and from within outward. No follicles can be seen along the laryngeal mucosa except one situated behind to the outer side of each ventricle just under the mucosa. Symmetrical gland groups exist in front of the arytenoids, which empty into the lateral cavities. There are also some glands in the midst of the muscle fasciculi, but none exist in front between the laryngeal cavity and thyroid cartilage. Some prearytenoid gland clusters are in contact with the perichondrium.

At the level of the vocal cord the same arrangement of the glands exist as in the pharynx. The arytenoid cartilages look like bobbins lying obliquely from in front backwards and from without inwardly and incurved in the shape of a leg of mutton whose knuckle bone runs alongside the posterior aspect of the laryngeal cavity. The lining epithelium of the laryngeal cavity is the stratified pavement type with absolutely flat superficial cells. The glands are situated between the thyroid cartilage and tip of the larynegal cavity and at this latter point large lobules exist (Fig. 5).

Below the epithelium the chorion is made up of loose connective tissue with very thin fibres. Adenoid tissue is diffused in the chorion in front of the laryngeal cavity.

The cavity of the ventricle is quite simple. Its contours are not geometrical, this being due to the folding of its walls. On the other hand, the appendix is represented by a system of sinuses and small ducts; the latter being veritable excretory ducts deserve particular mention, all the more so because macroscopically nothing can be seen that recalls accessory ducts near the principal cavity.

Hence the diverticular appendices represent a tubular prolongation directed from below upwards and backwards. Their longitudinal diameter is greater than the transversal, but the latter gives off numerous sinuses to the right and left which, by enlarging at certain spots, results in a most irregular aspect. The prolongation is lined with cylindrical epithelium *en plateau,* with ciliæ. Adenoid tissue is extremely abundant around the diverticula uniting many follicles together. We have been struck by the number and considerable size of these follicles, which decreases as one reaches lower down. This crown of peridiverticular follicles has been described by us in a normal larynx from a child four and a half years old who died from tuberculous meningitis.

We did not find this anatomical arrangement in sections of the larynx from a fetus of six months intrauterine life who died a day after birth. They did not exist around the diverticula in serial sections, while the adenoid tissue was merely represented by a few lines of cells. On the other hand, in serial sections made on a normal larynx from a female of fifty years, who died from pulmonary tuberculosis, the diverticula were bordered by a thick ring of adenoid tissue condensed at certain spots and nevertheless the follicles were quite as well differentiated as in the four and a half years old child.

The appendix serves as a depository for a multitude of gland clusters around it. These glandular groups, which empty into the cavity of the diverticuli, are embedded between the muscular fibres which lie between the cartilages and the diverticula. The glands, here and there confounded with the perichondrium of the thyroid cartilage in front and with that of the arytenoid cartilages behind, are embedded in a fibroconnective tissue which continues with the perichondrium of the arytenoid cartilages behind and laterally and in front with the thyroid cartilage.

This anatomical summary shows that the diverticulum in man should not be regarded as a resounding box. Its lumen is narrow, tortuous, riddled with glandular excretory ducts, lined with adenoid tissue which, in children of a certain age, is condensed into numerous follicles. To collect, as if in a reservoir, a liquid derived from numerous surrounding glands destined to lubricate the vocal cords, was a function long since referred to by Fränkel which, in our way of thinking, seems to fulfil the anatomical makeup of these diverticula.

From our personal researches we are inclined to suppose that, in consequence, these follicles offer a striking resemblance to a spread tonsil. This analogy has been suspected by anatomists. For example, Merkel looks upon the diverticulum as a large mucous crypt, while William Hill calls the ventricle —in the true sense of the word, but not the ventricle itself—the laryngeal tonsil and compares it to the monocryptic tonsil of the rabbit. Nothing better could be said, but from our viewpoint this appellation should be applied, not to the ventricle, but to its diverticular appendix, our researches having completed those begun by Fränkel.

The presence of adenoid tissue and follicles in the chorion of the mucosa lining Morgagni's ventricle was demonstrated in 1874 by Coyne in his thesis. This writer mentions about seven follicles in the walls

of Morgagni's ventricle almost constantly present in children in perpendicular serial sections made at the midportion of the vocal cords. The arrangement of the adenoid issue and follicles around Morgagni's ventricle was therefore an established fact in 1874, and there is nothing to add to these findings. Coyne indicates, among other things, the presence of two follicles which, in vertical sections, occupy the vault of the ventricle, one belonging to the ventricular aspect of the upper vocal cord, the other to that part of the mucosa covering the thyroid cartilage and subjacent muscles.

Nowhere is mention made of the very interesting arrangement of the adenoid tissue around the long prolongations sent off by the ventricles into the midst of the arytenoepiglottic folds. For that matter the diverticular appendices could not have been understood by the observers cited previously in the longitudinal sections of the larynx as published by them. With the exception of Fränkel, none have depicted them, and his description is more than summary from the viewpoint of the adenoid tissue. Now it is to this diverticular appendix, difficult to detect macroscopically, whose study can be undertaken only in serial transversal sections that, according to our way of thinking, one can apply the name of laryngeal tonsil. The crown of follicles which surrounds it in children is, in fact, uncomparably more developed than the adenoid tissue referred to around the ventricles.

Studying the diverticular appendix of Morgagni's ventricle in a premature six months fetus, we were extremely surprised to be unable to discover only a vestige of adenoid tissue at the site of this remarkable area of follicles. The appearance and development during early childhood of these follicles should therefore be envisaged as a process of defense of the organism to infectious agents, especially of the respiratory tract. This need of defense is entirely created by hypertrophy of the lymphnodes and follicles, the advanced sentinels against infection.

To conclude, Morgagni's ventricles and their diverticula have two functions, viz., they collect products of gland secretion destined to lubricate the vocal cords, they contribute to protect the larynx against external injuries and especially microbic invasion.

(To be concluded)

Sterility in Women*

A. KOPLOWITZ, M.D.,
Brooklyn, N. Y.,
Attending Gynecologist to Brownsville and East New York Hospitals; Assistant Obstetrician and Gynecologist to Kings County Hospital.

The subject of increasing sterility among highly civilized peoples has now become so important as to be regarded as a sociological problem of the first order. Throughout the world the birth rate appears to be in direct inverse ratio to the material prosperity and intellectual advancement of the races under consideration, so that it is now estimated that among the foremost peoples of the earth one marriage in every ten is childless.

Sterility in women may be due to any one of a number of causes. Several of these—such as fetalism, infantilism or certain infections—are readily recognized as definite bars to childbearing, but omitting these conditions from consideration, there are many cases which baffle the skill of the gynecologist. Frequently women will be seen in whom the closest scrutiny reveals no reason for sterility, who are married to healthy, demonstrably potent men, but who have failed to become pregnant during a number of years of married life.

Recent literature offers little that is new concerning the causes or treatment of sterility in women, and therefore, it seems justifiable to emphasize the only two recent advances in our knowledge regarding this condition. These two contributions are the etiological influence of endocervicitis so courageously upheld by Sturmdorf, and the diagnostic procedure of transuterine insufflation of the oviducts, originated by Rubin in 1920.

CLASSIFICATION

When a woman living in normal sexual relations has never conceived, her sterility is said to be primary; and it is customary to refer to primary sterility when a union has remained unfruitful for three years or longer.

Secondary sterility is the term applied to those cases where a woman has been able to conceive but through acquired causes is later rendered unproductive. Thus we have the patient who has given birth to one child, and thereafter acquired a postpartum infection which has prevented a repetition of conception, the socalled one child sterility; or again, the woman who, healthy at the time of marriage, has suffered a marital venereal infection, resulting in the production of pus tubes.

Female sterility is also classified as absolute when the cause—congenital or otherwise—cannot be removed; or relative, if the sterile condition depends upon the infertility of the male partner, or upon some factor which is amenable to surgical or other correction.

ETIOLOGY

Before considering the causes of sterility it is necessary to have in mind the conditions essential to the occurrence of normal pregnancy.

1. Female generative organs, anatomically and physiologically normal.
2. The deposit in the vagina of living healthy spermatozoa.
3. Retention by the spermatozoa of their viability and activity of movement for a time sufficient to enable them to find their way first into the uterine cavity, and then into the fallopian tubes.
4. The formation of a healthy ovum in the ovary capable of traveling into the tube to a point where it can be fertilized by the spermatozoon.
5. An unobstructed passage for the impregnated

*Read before East New York Medical Society, April 30, 1923.

ovum on its journey to the uterus, and a proper nidus in the subepithelial tissue when it has arrived at the uterine stroma.

Considering the first requisite, normal generative organs, we must remember that if the deterrent factors are congenital defects, they may, following Graves's classification, be divided into two main groups: fetalism and infantilism. Fetalism, a term first introduced by Alfred Hegar, is applied to the condition where a faulty or arrested development has occurred in intrauterine life, and is represented by such anomalies as nonunion of Müller's ducts producing uterus didelphys; or the various forms of aplasia, such as absence of vagina, uterus, etc., or their presence only in rudimentary form.

Infantilism, on the other hand, denotes that though the individual was born with a full complement of organs, development has been arrested, so that at puberty the sexual apparatus has remained wholly, or in part, that of a child. This may be the only sign of infantilism in an otherwise fully developed female, or, it may be but one manifestation of a condition of general hypoplasia. Thus, infantilism may usually be found in either of two types of women: one, the large, often fat woman who menstruates seldom or not at all, and on the other, the small, scrawny female who is not infrequently mentally defective as well. This brings us to the subject of endocrinology, for the development, as well as the physiology, of the genital organs is intimately related to the internal secretory functions. The anterior lobe of the hypophysis—as has been demonstrated by Biedl, Cushing, and others—controls the growth of the genital organs as well as that of other parts of the body, and the thyroid may also have some influence upon sexual development. The other endocrines, such as the adrenal cortex, play a rôle, if not in the development, at least in the functions, of the sexual organs. Likewise the interrelationship of the different organs of internal secretion, as between the gonads, the thyroid gland and the pituitary body, though seen and felt, is still far from being thoroughly understood.

In addition to fetalism and infantilism there are also conditions where minor defects, often susceptible of correction, exist which will be sufficient to prevent conception unless removed; for instance, a pin hole opening in the cervix. Only eight months ago such a patient presented herself to me with the history of eight years' sterility. On examination the cervical os could be found only with difficulty, and even after dilatation admitted only a one, two, and three size Hegar dilator. Yet much to my surprise, after a few dilatations the woman became pregnant.

Malpositions and flexions also come under our first heading. A retrodisplacement of the uterus may, by throwing the cervix under the symphysis, prevent spermatozoa from gaining access to the uterus. In the words of Arthur E. Giles, the English gynecologist: "The os looks so far forward that during intercourse it is pressed against the anterior vaginal wall, which thus closes over the os like a lid, and so effectually prevents the entrance of spermatozoa." This author's tables show that among 530 cases of primary sterility, retroversion was present in fifty-four, or 10.2 per cent. Marked anteflexion or retroflexion may operate in the same way. That the flexion can in itself mechanically obstruct the passage of spermatozoa, is denied by most authorities, because, as is selfevident, if the flexion will permit the menstrual flow it would certainly permit the entrance of the microscopical spermatozoa. Yet, even then, congestion and inflammatory changes at the internal os or below it induced by the displacement, may bring about sterility. New growths in the uterus, such as those of malignant diseases, and—to a smaller extent—myomatous changes, may likewise be causes of sterility.

In addition to anatomical anomalies there are also the physiological dysfunctions which are sufficient to prevent childbearing. Dyspareunia means difficult intercourse or the inability to perform the act without pain, and is more commonly applied to the female. The condition may arise any time, but is usually seen in the newly married. Generally it is due to some pathological condition, such as vaginitis, the existence of a small urethral caruncle, or extreme tenderness of the carunclæ myrtiformes. In examining a case of dyspareunia it should be borne in mind that unless carefully sought the lesion may be so small as to escape notice altogether.

Vaginismus, although only a neurosis, is a terrible affliction to any young woman. It was first described by Marion Sims who is quoted by Gibbon as designating it as "an excessive hyperesthesia of the hymen and vulvar outlet associated with such involuntary spasmodic contractions of the sphincter vaginæ as to prevent connection." The gentlest touch will cause a spasm of the powerful levator ani and the other muscles around the vaginal outlet, producing such a contraction that, not only is it impossible for the male organ to enter, but it is even impossible for the gynecologist's finger to gain access for examination. The condition usually exists in women of neurotic type, and may be brought about either by lack of virility in the husband at the beginning of married life, which leads to unsuccessful attempts at coitus, or to ignorant brutality in the male approach, which at times not only induces fear, but very likely frigidity, as well. Frigidity in itself, however, is not necessarily a cause of sterility, for we all know of cases where conception has taken place in spite of lack of sexual desire.

STERILITY INDUCED BY PATHOLOGICAL CONDITIONS

Coming now to those acquired conditions which, in a previously healthy woman, have brought about changes which have caused her to become sterile, we will find that recent advances in pathology have not only increased our knowledge of these conditions, but placed us in a position to help at least a portion of those unfortunates who apply to us for relief.

The epoch making investigations of Hitschman and Adler have proved that the corpus uteri withstands most infections, seldom becoming inflamed. They "hold that the only true endometritis is that of the interstitial type; that the socalled glandular endometritis does not exist, but that most of the appearances hitherto described as such, are merely physiological changes in the glands occurring in the course of the normal menstrual cycle, and that when glandular hyperplasia is definitely present it is more of the nature of a new growth than of an inflammation." It is well known that, in the majority of instances, even the gonococcus, though it travels

directly through the uterus to the adnexa, rarely affects the uterine mucosa. Of course, there are virulent invasions able to overcome even the resistance of the endometrium; also tuberculous conditions, but they are rare.

It is at the neck of the uterus that the real obstacle to conception most often exists. As has been emphasized by Sturmdorf, the cervix is by far the most important element in causation of sterility, at least so far as infections and inflammatory changes are concerned. Not only does the presence of the plug of mucus in itself act as a mechanical obstruction, or the discharge of pus prove sufficient in a great many cases to kill all spermatozoa seeking entrance, but also, as Sturmdorf has shown, the infection traveling to the adnexa through the lymphatics can cause that chronic condition which he aptly calls periadnexitis, called by others pelvic inflammatory disease, and in this way produce constriction in the oviducts so that they do not permit of passage of ovum or spermatozoon. This is a much more absolute bar to conception than the artificial ligation of the tube, which, as shown by Fritch and others, does not in all cases bring about sterility.

The endocervicitis causes an ascending lymphangitis which travels along the muscular planes of the uterus and tubes, and, reaching the ovary, thickens its capsule and interferes with the normal rupture of graafian follicles, forming retention cysts of the ovary and thus adding ovarian functional insufficiency to the pathological chain. The lymphatics drain into the larger vessels on the outer surfaces of the uterus and tubes, often producing the cobweb adhesions between the pelvic organs, which so often bring about constriction of the tube. In its upward journey through the uterine lymphatic system, the infection naturally infiltrates the muscle bundles themselves and in this way inhibits uterine contraction. The consequence of this is interference with the uterine circulation which, because of the valveless veins in the uterus, requires those contractions. The resulting engorged endometrium forms a very poor site for ovular nidation. Associated nutritional changes often bring about early abortion for which no cause is assignable. Such an abortion is often believed to be a delayed menstruation, as in the woman who several times a year goes a week or two over her period and then menstruates, though at other times she menstruates regularly.

On reaching the tubes the infection leaves its mark there by the periadnexitis which occludes the fimbriated ends and the formation of adhesions which will naturally cause the kinks so often found in abdominal sections. In time the passage of the disturbed circulation through the walls will cause a true salpingitis.

Though endocervicitis may be acquired after marriage we often see it before marriage; even dating from childhood. Many girls presenting themselves for treatment for dysmenorrhea and other menstrual disorders give an associated history of leucorrhea, usually of long standing, and acquired either in infancy, in school or elsewhere, and we all know how intractable is the socalled vaginitis of children. I say socalled because most of these cases are actually a true endocervicitis.

This endocervicitis does not always reveal itself by the characteristic erosion; the external os may appear normal except for the telltale discharge which we must learn to recognize and treat. Without endocervicitis there can be no cervical discharge recognizable by the patient, and dysmenorrhea likewise is usually present. By recognizing this condition even when inspection alone fails to reveal it we will be in a better position to understand the consequences already described.

The result of this ascending infection on the uterus and adnexa is often impossible to detect by bimanual examination, because the bands and kinks are impalpable and the ovary and uterus may not be painful to the touch. Here it is that the second great advance in our present knowledge of sterility has been made by Rubin through his positive demonstration of the patency or nonpatency of the fallopian tubes, by passing oxygen or carbon dioxide through the uterus and tubes into the peritoneal cavity; failure of the gas to pass indicates that the tubes are occluded.

As in all other advances in sciences the very simplicity of the idea emphasizes its greatness. The technic is simple and, like all such procedures, is best carried out with the special apparatus designed by the inventor and in the same manner as performed by him. Rubin's instrument not only gives the pressure under which the gas flows, thus showing whether an obstruction exists and if so, its extent, but also when there is no obstruction it estimates quite accurately the amount of gas introduced into the peritoneal cavity, thus obviating the discomfort and, at times, shock, caused by the introduction of too much gas. Oxygen may be employed, though it is not quite so good as carbon dioxide which, being more readily absorbed, naturally causes less discomfort, though even with oxygen this is at no time unendurable. The test is best made in an institution, unless the operator has an x ray outfit in his office. While one can judge by the pressure which rises steadily in the nonpatent tube, in contrast to the rise in the open tube to 100, then 150 mm. followed by a drop to 80 to 60 mm. as soon as the gas flows through, or, by the characteristic pain in the left shoulder due to the gas rising to the left hypochondrium, it is still better to use the fluoroscope so as to be able to see the shadow of the gas in the peritoneal cavity. One main contraindication to this test is any inflammatory disease of the generative organs, but in most of such cases we do not need the test.

The second factor necessary to conception—normal, healthy spermatozoa—is selfevident and needs no discussion, but the third, that the spermatozoa retain their viability and motility so as to enter the os and the uterine cavity brings us to the consideration of agencies which may hinder that accomplishment. Hyperacidity of the vaginal secretions may overcome the alkalinity of the semen, killing the spermatozoa or inhibiting their activity. The vagina may be so shallow that the semen flows out before the spermatozoa can find their way into the cervix. Effluvium seminus—the flowing out of semen from the vagina after coitus—is said by Runge to be a frequent cause of sterility; but the finding of a history of this condition in seventy-nine per cent. of sterile women is not, in itself, a sufficient reason for in-

fertility. Huhner, who has made extensive studies of the mechanical reasons for sterility, found in a fair sized series that this condition exists in eighty per cent. of women who have had children. As mentioned previously, the position of the cervix in relation to the vagina may render it difficult or impossible for the cervix with its open os to dip into the seminal pool, and, let it be repeated, the frequent presence of endocervicitis in various ways may prevent the spermatozoa from fulfilling their destiny.

In regard to the fourth and fifth conditions it naturally requires a normally developed and generally healthy ovary to produce healthy ova, likewise a clear passage through normal oviducts and a proper site for the embedding of the ovum in the uterine mucosa. There are, however, other causes for sterility which are outside of these five postulates.

Reynolds and Macomber, of Boston, as a result of their feeding experiments on rats, assert that diet is an important element in the causation of sterility. Admitting the difficulties of comparisons with human beings who enjoy a far more complex and generally sufficiently variated diet, and that "the life conditions of the human race are much more complex than those of laboratory rats," they still believe that, "peculiarities of tastes or mistaken dietary theories not infrequently lead to the choice of a diet which is insufficient in one or the other of the vital elements." They further remind us that although infertility in a given case, with definite anatomical or pathological conditions, demands operation there may still be need of attention to accessory constitutional conditions before a cure can be effected.

Obesity is frequently associated with sterility, Gibbons estimating that the percentage of barrenness in the obese is twice as high as that of women of ordinary weight (that is, about twenty per cent.).

Yet, with all necessary conditions fulfilled there remains that class of cases where the spermatozoon alive and active in the tube does not impregnate the healthy ovum. "That many individual infertilities are functional rather than due to anatomical or pathological causes; that very moderate decrease of fertility in both individuals may produce a completely infertile mating; and that," as Reynolds and Macomber believe to have been proved in their feeding experiments, "two rats that are infertile to each other may both be fertile to other individuals, not because of obscure incompatibilities, but merely because of a decreased percentage of fertility in each," are points worthy of much consideration, and much in need of further study and elucidation.

TREATMENT

Leaving out those causes of sterility which are irremediable the treatment in cases at all possible of cure must be undertaken with a due regard to all the causative factors. Reason demands that no set rules be followed and no pet hobbies ridden. The administration of animal glandular substances to every patient is as irrational and as injurious to excellent therapeusis as the recommendation of operation in every case. Endocrine therapy is yet in its infancy and its fundamental principles not yet mastered. Nevertheless, in spite of the many disappointments we encounter, its possibilities seem almost limitless; we often meet with such brilliant results that we must feel encouraged for the future. But, in adopting it in a given case, due care must be exercised not to overlook other etiological factors upon which all the glandular substance in the world will have no effect. In such cases as ovarian dysfunction or thyroid hypofunction the appropriate exhibition of gland therapy will show quite gratifying results.

Though the question as to whether to use the ovarian substance itself or corpus luteum is still in debate, most authorities seem to favor the whole gland, leaving the use of corpus luteum to those conditions where its presence is known to be necessary, dysfunction leading to such conditions as the hyperemesis of pregnancy.

The large heavy woman with much diminished menstrual functions will frequently respond to thyroid therapy. In cases of infantilism, with at least occasional menstruation, administration of the anterior lobe of the hypophysis which controls the growth of the genital organs, will at times prove efficacious. Conditions of malposition quite often cease to operate as causes of sterility after correction by pessaries or surgical treatment. Flexions in themselves seldom cause sterility, but the resulting congestion and blocking of drainage is often corrected by a stem pessary—preferably made of glass—the results at times being quite satisfactory. But when the retrodisplacement is associated with endocervicitis, nothing but the cure of the infectious condition will prove of any benefit.

Endocervicitis is simply and easily cured if one is guided by immutable facts. Local treatment of all sorts will remedy the great majority of cases of real endocervicitis, as well as the douche will cure its resultant leucorrhea. To be sure, there are simple inflammations in the cervix which do not infect the upper organs and do not cause sterility, but when the inflammation shows its virulence by dysmenorrhea and other symptoms of upward extension there is only one course to pursue, and that is, the enucleation of the cervical mucosa.

When we remember the histological anatomy of the mucous membrane lining the cervix we shall realize how difficult it is to treat appropriately the abundant racemose glands which dip into the muscle tissue itself and are always infected. Stopping the discharge does not cure the deep seated infection. Curing the erosion is only removing one of the results, leaving the underlying condition untouched. All of us who at any time have attempted to treat endocervicitis are aware that the troublesome case will at times show improvement under treatment, but in time the infection makes its appearance again, showing that our labors, and the poor patient's time and endurance, have been wasted, for all the time the infection in the glands has been active, even though showing no outward signs. A long time ago Schroeder recommended extirpation of the infected area, but his technic removed too much of the muscle tissue itself and left too much of the infected mucous membrane. The enucleation, as taught by Sturmdorf, removes the cervical mucosa, with a thin layer of muscle, up to the internal os and covers the denuded area by a previously dissected cuff of vaginal mucosa, thus curing the endocervicitis for all time. If the damage done to the upper organs has not been too extensive the restored balance will enable the

fighting powers of the organism to conquer the existing infection, once the supply of the poison is cut off.

Functional disturbances must be treated according to causes. Dyspareunia will require the removal of the local lesions, and vaginismus, being a neurosis, must be treated as such.

It seems probable that errors of diet, though at times undiscovered and unlooked for, are a real cause of sterility and further investigation along these lines and the correction of dietary errors will clear up an otherwise unintelligible case.

Leaving to the genitourinary specialist those other considerations which more properly belong to him, I wish to call attention to the fact that every case of sterility demands of the practitioner of medicine as much time, patience, and perseverance as any of the great problems which constantly confront him, and that a multitude of factors are to be considered, some of which at times seem trivial, yet if neglected, success cannot be attained.

We are today in a better position than ever before to help the unfortunate who applies to us, and nothing but the very best that is in us should be brought to her assistance.

Geriatrics as a Special Branch of Medicine

MALFORD W. THEWLIS, M.D.,
New York

It would perhaps be advisable to speak of giving special attention to senile patients, rather than to suggest a new specialty in an already overcrowded field. Medicine has become so highly specialized, however, that one feels free to discuss geriatrics as a special branch of medicine.

Only a few years ago pediatrics did not exist. Before 1860 little attention had been given to that subject. One small textbook had appeared which was entitled *Diseases of Women and Children,* and there was one chapter in it devoted to the latter. Abraham Jacobi, the Nestor of American medicine, was the first to begin a systematic course in pediatrics and in 1860, when he instituted this study in New York, the announcement was removed from the bulletin board of the college because the dean contended that pediatrics did not exist. Jacobi wrote on pediatrics and was ridiculed. A few students were interested in the subject, but the enlistments in the Civil War brought about a discontinuance of the course.

Jacobi patiently continued his researches, trying to convince the medical profession that diseases of children could not be treated like those of maturity. He faced a similar opposition when he performed tracheotomy so many times with many failures. Nothing could convince him that his theories were wrong and he lived to see the day when his work was internationally known and recognized.

Geriatrics (Greek, *geron,* old man; *iatrikos,* medical treatment) is that branch of medicine which deals with diseases of old age. It includes the prevention of premature senile changes and the care of the aged. German and French physicians had given some attention to the study of diseases of old age, but it passed into oblivion, to be resurrected only a few years ago.

Hippocrates made mention of some of the peculiarities of old age, and in 1537 Stormer wrote *Decreta Medica de Senectute.* In 1666 John Smith brought forth *The Pourtraicture of Old Age* published in London. Floyer's *Gerocomica* was printed in London in 1724 and its original form is an interesting book. Charcot's lectures on old age were published in Paris in 1866 and Dr. Loomis's translation contained some of his own lectures. The first textbook printed in English was published a few years ago by Dr. Nascher, who made an exhaustive study of the subject.

At its birth, geriatrics was treated exactly as pediatrics had been; physicians failed to understand that diseases of old age required special attention. Like every new subject, geriatrics met with scepticism and occasionally with open scorn.

Barring the New York Geriatric Society, there was no society, medical journal or medical school which gave any consideration to geriatrics. Today, medical journals throughout the country have given editorial consideration to this subject, and the lay press is realizing its importance. It is not only a medical problem but an economic one, because the more ineffective old people the heavier are the demands on State charities. Providing work for the aged to make them selfsupporting would not only relieve them of many ill feelings but cause less drain on State funds for their support.

The aged will never appeal to physicians as the children do, to specialize in their diseases does not present the same financial opportunities nor the same possibilities of cure. Physicians commonly call a disease "old age" and say that nothing can be done for the patient. Again, the latter's family does not always show keen interest in the aged relatives.

A little attention and care will often have wonderful results. When ill, an old person requires special treatment because Nature tends to cure the young and kill the aged. Applying the rules of treatment at maturity will often produce disastrous results with the aged. For example, in treating the latter it is absolutely necessary to keep patients out of bed; being kept in bed impairs the circulation, besides the psychic effect is not to be overlooked. "Keep senile patients out of bed" should be a slogan in geriatrics.

In going over our best works in literature, art, poetry and the sciences, we find that we are much richer for the brains of many old men and women, and the works of men past eighty have been a mint of knowledge. Indeed, their activities often increased as they grew older.

Senility does not begin at any given age, as it may begin at sixty or seventy, but it sometimes begins very much earlier in life. I recently saw a woman of thirty-two who had chronic nephritis, arteriosclerosis and cardiac hypertrophy, which were not due to any specific cause. In every way she showed degenerative changes consistent with a person seventy years of age and she should, therefore, come under the treatment of geriatric patients.

The age of the patient does not matter as much as the evidence of senile degeneration he shows. As a rule, most people begin to develop some senile changes at fifty and if these were noticed many serious degenerative changes could be prevented. As geriatrics includes the study of old age, of the causes which produced the changes inherent to it, many patients past the age of fifty would come under this geriatric care.

Arteriosclerosis and many of the senile degenerations depend upon nephritis and other diseases which, if treated, would prevent further pathological changes. In women many conditions developing at the menopause can undoubtedly be corrected by proper organotherapeutic measures.

By far the greatest mistake in treating old patients is to endeavor to produce results which would be normal to maturity. It is useless to give potassium iodide for arteriosclerosis, because the latter is a normal process of advancing years and does not require treatment. If we attempt to obtain results consistent with normal senile changes, we have the keynote of geriatrics. We must always strive for the norm of senility and this cannot be done without a knowledge of the pathology of the senile state. In old age all organs undergo degenerative changes, but as long as these diseased organs functionate in harmony there is no untoward result. The physician who applies ordinary therapeutics to senile patients is often unsuccessful.

The treatment of diseases of old age is a study by itself. Small doses of remedies will often produce better results than larger ones. Morphine used hypodermically sometimes causes sudden death in old age because of respiratory paralysis and it is, therefore, always safer to combine it with atropine for hypodermic use in order to prevent this harmful action on the respiratory centre.

One of the most common conditions met in old age is insomnia. Physicians often give morphine to make the patient sleep when a placebo would do as well. The aged frequently nap in their chairs during the day and when night comes they cannot sleep; to give morphine in such cases is inexcusable. Moreover, the aged do not require as much sleep as younger people and sometimes they will deny having slept, when they actually have. In some instances they will not tell their symptoms if they believe they can thus avoid an examination. In others, they will invent every known symptom, sham illness, in order to excite sympathy. Because of diminished sensibility, it is possible for an old person to have appendicitis or peritonitis without pain. The aged are as difficult to treat as children; while a child cannot tell its symptoms, an old person cannot seem to tell the truth about them. In fact, it is often easier to treat infants; they cannot lie.

Toxemias of the aged are interesting studies. Uremia will often cause symptoms similar to those of cerebral hemorrhage. Many of these patients recover under optimistic and proper treatment. A physician who works upon the theory that "nothing can be done for the aged" should not treat senile patients. Hope, carefully instilled, will sometimes pull a patient through a serious illness when nothing else will. The treatment of senile patients requires much patience and therapeutic optimism.

Many old people who are suffering from hemiplegia can be made effective again by the method of functional recuperation of Dr. Gabriel Bidou, of Paris. This is done by means of springs which replace paralyzed muscles, and enable the patient to walk again.

The secondary effects of drugs due to faulty and slow elimination must be considered because oftentimes they are more important than the primary effects. In the aged, opiates may remain in the body for several days and cause drowsiness two or three days after its administration. Again, opiates will often cause mania instead of quieting the patient. In fact, many remedies have a diametrically opposite effect from that commonly observed in maturity. In treating senile heart disease, we must resort to methods different from those we are accustomed to use.

So much depends upon the understanding of the senile organism, upon the little details that go to make life more comfortable for old persons; so much depends upon the attention and sympathy given them and upon keeping them occupied as much as possible. Two things are most necessary in this study; first, a careful routine examination of all patients, and, second, a knowledge of normal senile pathological changes. There are so many problems connected with geriatrics that its study should be more encouraged and there should, in my opinion, be special courses, of a few lectures at least, in the curriculum of medical schools; clinics should be established where the proper laboratory work could be done and where postmortem examinations could be made in order to check clinical findings.

No doubt many will disagree with me about the importance of geriatrics, but old age faces all of us sooner or later and I feel sure that when it does, we should not care to be practically cast aside or allowed to suffer from disease because it is taken for granted that we are too old to be successfully treated. The term old age applied to a patient is too often a death warrant.

Practical Therapeutics

TREATMENT OF ACUTE METASTATIC ARTHRITIS*

M. B. Cooperman, M.D.

Philadelphia, Pa.

Associate in Orthopedic Surgery, University of Pennsylvania, Post-Graduate Medical School.

Every case of acute metastatic arthritis is a surgical lesion. The morbidity and mortality of these affections depend upon the realization, by physicians generally, that it is not a medical condition to be treated by salicylates, coal tar derivatives or local applications. The treatment of these acutely infected joints must be prompt and decisive. Procrastination dooms the patient to an extension of the pathology and the likelihood of restoring the function of the joint becomes more and more remote.

This type of arthritis is usually secondary to a primary focus of infection in some part of the body. When metastatic involvement of the joints is initiated by a chill, one joint, at least, will have bony ankylosis as a sequence of the infection, unless it be managed along other lines than those in which such joint involvements are usually treated.

Medical men must appreciate the fact that whenever a joint is infected, it presents certain inflammatory phenomena. These are manifested by an effusion into the joint which distends its capsule and separates the articular ends of the bone. A mild irritation by bacterial agents produces an infectious synovitis with exudation into the joint space. Bacteria or their toxins irritate the secretory layer of the capsule and produce one of three types of effusion—serous, serofibrinous or purulent. The secretion of the exudate is Nature's attempt to dilute and neutralize the poison. If the poison or toxin is mild, a serous exudate is poured out; if it is more irritating, this exudate becomes serofibrinous. When the barrier offered by the secreting layer is inadequate, bacteria in great numbers enter the joint cavity and purulent synovitis is produced.

The fulminant types of arthritis are those in which the joint is invaded by an overwhelming number or avalanche of bacteria before Nature has had a chance to throw out enough exudate to dilute the toxins or destroy the organisms. There is a rapid destruction or melting away of every element of the joint, bone, marrow, cartilage, etc. If aspirated in the early stage of this inflammation, no organism will be found in the fluid. Later, however, the bacteria gain entrance into the joint cavity. These facts demonstrate the importance of withdrawing the fluid in the early stages.

The principles underlying the treatment of these various phases of joint inflammation are simple:

Relieve intraarticular tension by removing fluid and separating the articular surfaces of the bones. Put the joints at rest until the inflammatory reaction has subsided. Encourage active motion early, when the synovial capsule only is involved, but under no circumstances must it be employed when bones are infected. Remove all débris from a joint that has undergone destruction; the sooner this is done, the less likelihood is there of extension of disease, deformity and metastases to other parts. Clean up the primary focus of the disease, increase the resistance of the patient by a nutritious diet, tonic medication and sunlight; finally, occupational therapy is one of the most beneficial agencies in restoring joints stiffened by adhesions.

John B. Murphy treated these cases by removing fluid from the joints and by the injection of two per cent formalin in glycerine; thus was produced a defensive reaction within, preparing, as it were, a barrier against invasion from without by neutralizing the infection. This treatment was followed by marvelous results. I have used this method not only in treating arthritis, but also in tuberculous joints, substituting Calot's fluid for the formalin, and have had satisfactory results.

Joints should be punctured to determine the character of the exudate. It is a measure frequently neglected but of great diagnostic import. Many physicians are averse to puncturing the distended joints, fearing added infection to the joint cavity. To this I must take exception, for when done carefully and with due attention to asepsis, it is indeed a harmless and valuable procedure. No one can tell what is going on within the joint unless the fluid is bacteriologically examined, and in the event of a bacterial invasion, we are in a better position to institute rational measures for combating it. It is my belief that many joints permanently destroyed, could have been saved by punctures and repeated aspirations. It is very curious to note how frequently spinal punctures are performed, with impunity, to relieve cerebrospinal pressure, and yet when the indication exists in a joint, physicians hesitate to relieve intraarticular pressure.

When performing a puncture or aspiration, the joint to be aspirated should be surgically prepared as for a major operation, the operator's hands scrubbed and gloves used. A hypodermic needle of medium calibre is employed and the joint is entered at its interline.

If the effusion is a clear colored serous fluid and sterile, the joint should be aspirated, the limb put at rest in a light plaster cast or splint; at the same time, traction is employed wherever possible. The reduction of intraarticular pressure relieves the pain more promptly than aspirin, morphine or any local sedative. If the fluid reaccumulates, aspiration is repeated every third or fourth day. After ten days of this treatment, the affected joint will more readily respond to the aftertreatment because the capsule and periarticular structures have not been permitted to become distended. The probability of adhesions forming is reduced to a minimum.

If the fluid is serofibrinous in character, aspiration should be employed and repeated at brief intervals. The withdrawal of the fluid prevents organization of this exudate into fibrous adhesions so frequently a sequence to this form of inflammation. If the fluid cannot be aspirated because it is too thick and turbid, irrigation of the joint is indi-

*Read before the Southeast Branch of the County Medical Society.

cated. In the knee joint, for instance, two needles penetrate on each side of the patella at the interline of the joint. Through one the fluid is removed, and into the other the saline solution enters. If the fluid still remains turbid, and the symptoms do not abate, it is then necessary to perform an arthrotomy. Taking the knee again for an illustration, an incision is made in each side of the patella through the capsule, the fluid is drained and the joint thoroughly irrigated with normal saline. No tubes are inserted. The arthrotomy wounds can usually be closed at the end of a week or ten days. Traction is invariably employed. Active motion is encouraged.

If the puncture reveals pus, the joint should be freely opened by wide incisions of sufficient size to provide adequate drainage. This is very important. No tubes of any kind should be utilized because they only irritate the joint. If used at all, they should not remain in any longer than forty-eight hours. Active and passive motion is continued both night and day. Spontaneous closure is not permitted. This is the Willems method of treating these cases, a method which is sometimes very hard to enforce, especially in children, because of the pain, and unless there is a well organized staff of nurses to encourage such patients, it is a difficult procedure. But, whenever indicated, it is attended with satisfactory results.

It must be emphasized that care must be exercised in the selection of the case for this form of treatment. I have known of two patients with arthritis of the knee on whom Willems method was tried with disastrous results. We realized later that it was ill advised. In one patient a metastatic abscess developed in the thigh which required incision and drainage. The other had acute osteomyelitis of the femur and a pyoarthritis of the knee. After evacuation of the pus through wide incisions, this patient was encouraged to move the joint as much as possible. An extensive suppuration of the facial plane of the thigh and phlebitis subsequently developed and the patient died of a streptococcic septicemia.

Sir Robert Jones states that, among the soldiers, fifty per cent. of cases resulted in a useful degree of mobility. Many patients suffering from suppurative synovitis in whom this form of treatment was employed, became much interested in the carrying out of the exercises, so when the joint became painful, they would express the pus by voluntary flexing and extending the joint.

There is a form of infectious arthritis to which this treatment must not be applied. I refer to those cases where all structures of the joints are involved, the bones to a considerable extent. After the fluid is drained, fixation is indicated. Motion, even to the slightest degree, would tend to increase the inflammation, causing pain of the most excruciating kind. The articular ends of the bones literally melt away, pathological dislocations occur early and ankylosis with deformity is the usual result. There is only one type of treatment that will save life and limb, and that is wide exposure of the joint, trephining and curretting the infected bone, if necessary, instituting free drainage, followed by fixation in plaster and weight extension. In some cases, excision must be considered, an undesirable thing to do in children, because there is the inevitable loss of an epiphysis with arrested growth as a consequence. It is unavoidable, however, when a profound sepsis is present, which can only be allayed by removing rotten bone.

I have had the privilege of treating a number of acutely infected hip joints at the Mount Sinai Hospital. There was a remarkable case of acute panarthritis in the wards at the time this paper was written, a nine year old child, on whom a rational treatment had been used, which, I believe, saved his life. For three or four days after admission, the diagnosis was in doubt, but the clinical course, eventually, led to a diagnosis of an acutely infected hip joint. The x ray was negative. An incision was made into the thigh to institute drainage. The condition improved slightly. Subsequently, another opening had to be made to provide more adequate drainage. This also proved ineffective, and the condition became desperate. The child was extremely septic and suffered intense pain. The temperature range was of the typical pump handle type, pulse weak and thready. The hip joint was markedly distorted, being flexed and adducted to the superlative degree. One could not get near the bed. Merely touching it would make the child cry out in pain. It was a pitiful case and it looked as if the child would die. An x ray examination made at this time showed a widened joint space and osteomyelitis of the neck of the femur. The joint was then exposed through anteroposterior incisions and the cavity thoroughly irrigated with normal saline. A through and through drainage tube was inserted. Adhesive straps were applied to the thigh for weight traction and a plaster of Paris cast from the thorax to the toes was applied. A window was cut in the cast for dressings. The next day, the child was free from pain and rested quietly. The temperature dropped gradually and in two weeks one could scarcely recognize the child, he had improved so remarkably. This case teaches that adequate drainage, fixation and traction should never be forgotten.

Another case of acute arthritis of the hip developed in a child five or six years old upon whom a radical mastoid operation had been performed for acute mastoiditis and sinus thrombosis. The temperature continued high, even after this operation, ranging from 103° to 106°. The child was decidedly septic and the blood revealed streptococcus hemolyticus. He suffered extreme pain in the right hip. The examination revealed a sensitive hip joint held in a flexed and adducted position by marked spasm of the surrounding musculature. A diagnosis of metastatic arthritis of the hip was made, from the suppurating focus in the mastoid. The radiographic examination of the joint was negative. No fluid was obtained by diagnostic puncture. The hip was immobilized by sand bags and five pound weight extension was applied to the extremity. The temperature came down to normal, pain diminished and disappeared altogether at the end of ten days. In three weeks the child had entirely recovered both from the mastoid and hip complication. An acute arthritis of the hip following acute mastoiditis is an unusual complication.

Neglected, the probable course of this case would have been a destruction of the joint cartilage, with ankylosis and deformity. One must never overlook the fact that Nature in her effort to splint an in-

flamed joint by inducing a state of spasm in the muscles, forcibly approximates articular surfaces, causing adhesions or destruction of cartilage and bone.

Another child in the wards of the hospital at the same time, aged ten years, had a bilateral pathologically dislocated hip joint. During the epidemic of 1918, a bilateral panarthritis developed following influenza. Unfortunately, he was held back too long, and by the time the surgeon was called in there was already a pathological dislocation. Both hips had to be opened and drained. He had draining sinuses which finally closed after eighteen months. Three years later, I operated upon his right hip joint to correct a vicious deformity. Just recently, a sinus opened leading to the left hip. This case is an illustration of belated surgical intervention.

PREVENTION AND TREATMENT OF DEFORMITIES

Acute polyarthritis of metastatic origin is usually treated in the medical wards and whether the cause be the gonococcus or the staphylococcus, influenza bacillus or any other pyogenic organism, it is a familiar observation to note that the treatment consists mainly in the administration of drugs, vaccines and local sedatives. Very little, if any attention, is paid to splintage and extension. The usual termination of this disease is for all the joints to clear up except one, which usually becomes ankylosed in a faulty position. The hip joint, for instance, becomes pathologically dislocated in a position of flexion and adduction, the upper margin of the acetabular cavity is usually eroded and permits the femur to be displaced upwards and backwards on the ilium. The knee usually assumes a pathologically flexed position held so by accomodative contraction of the hamstrings and posterior ligaments of the joint. The destruction of the cartilagenous surface contacts bone to bone, which leads to a bony ankylosis. From a preventive viewpoint, fixation and extension should always be applied to the joints of the lower extremities when acutely or chronically inflamed. If ankylosis be the inevitable outcome, they are then in the best position for weight bearing.

If the limb be already deformed, corrective measures can be employed either in stages without anesthesia and an application of casts or the deformity can be corrected, under an anesthetic, by manipulation and the division of shortened tendons and ligaments. I have treated a series of pathologically flexed knee cases at the Philadelphia Hospital. These I corrected by manipulation without anesthesia and the application of casts.

A word in connection with the removal of infected foci in the treatment of acute infectious arthritis. Patients must be carefully prepared for the removal of these foci, even waiting some time until a greater resistance has been acquired through building up, rest, diet and tonic medication, before subjecting them to a large dose of toxins when they have already been seemingly overwhelmed.

The joints during an acute flareup should not be baked, massaged or manipulated, because they themselves may be the foci of infection. Protection, warmth and any application which gives local relief, is indicated.

In conclusion, I want to make a plea for more complete cooperation between the general practitioner who first sees these cases and the surgeon. There are too many cripples walking the streets today, who, had they secured the proper treatment at the right time, would have been spared the tremendous handicap forced upon them by belated treatment or crass negligence.

2017 Pine Street.

TREATMENT OF COLON BACILLUS INFECTIONS OF THE UPPER URINARY TRACT WITH AUTOGENOUS VACCINE

Albert M. Crance, M.D.

Geneva, N. Y.

A review of the literature on the subject of autogenous vaccine in the treatment of colon bacillus infections of the upper urinary tract is rather scant and few conclusions can be drawn as to the results obtained. It has been generally admitted that vaccines, including autogenous vaccines, in streptococcus and staphylococcus infections of the urinary tract have not yielded results good enough to warrant their use as a standard method of treatment. This is not true, however, when the colon bacillus is responsible for the infection.

Colon bacillus infections in the urinary tract are by far the most common and it occurs much more frequently in women than in men. It may be found confined to the bladder, to one kidney and the bladder, or to both kidneys and the bladder. The bladder being affected in all cases, there are always symptoms which go along with cystitis.

Routine culture from the catheterized specimen should be obtained, including a culture from both kidney urines. If the culture shows colon bacilli with streptococci or staphylococci, an autogenous vaccine will not produce the results that it will when the cultures are pure Bacillus coli. When such mixed infections occur, autogenous vaccines, lavage of the renal pelvis on the side infected, together with the removal of foci of infection such as infected teeth or tonsils will undoubtedly produce good results.

TECHNIC OF TREATMENT

I desire in this paper to discuss the method of treatment in cases showing a pure culture of colon bacillus with the report of some typical cases. The vaccines used are made from the patient's culture showing the colon bacillus, with a dilution of one billion to the c.c. The best results are obtained with large doses beginning with 0.5 c.c. injected intramuscularly either in the arm or the buttocks, repeating the injections every five or six days, doubling the dose each time until it has reached two c.c. From eight to ten injections are usually sufficient. I have tried the customary method of giving smaller doses over perhaps a longer period of time and with discouraging results. Larger doses of the autogenous vaccine adminstered every five to six days have given excellent results.

REPORT OF CASES

Case I.—Female, aged twenty-six, married, referred by Dr. Neider, February 28, 1923, complain-

ing of marked frequency of urination associated with severe hematuria. The patient had had symptoms of bladder involvement with two former attacks of hematuria since her confinement some twelve months before, having been perfectly well previously. Cystoscopy showed a severe cystitis with a small bleeding ulcer midway between both orifices. This was fulgurated to check the bleeding. The culture of catheterized urine showed a pure growth of colon bacillus. An autogenous vaccine was made and administered every six days by her physician, using the dose outlined above. After the last few injections she was entirely well and now, six months later, she states that she has no symptoms and has had no recurrence of bleeding from the ulcer which was undoubtedly caused by the infection.

Case II.—Female, aged forty-seven, married, referred by Dr. Skinner, complaining of frequency and urgency of micturition with the history of having had the condition for about five years. Cystoscopy and ureteral catheterization showed pure colon bacillus growth which was confined to the bladder sample. An autogenous vaccine was made from it and treatment given in the same manner and almost immediate results followed. The patient received nine injections. She was considerably improved after the third, and after the last injection the patient was free from the symptoms and now three months later she states that the symptoms are absent.

Case III.—A female child, aged seven, seen April 17, 1923, in consultation with Dr. Butler and Dr. Hatch, of Penn Yan, N. Y., complained of obscure symptoms which began with a distended abdomen and a fever ranging from 100° to over 105°. There was also vomiting. The child did not complain of any particular urinary symptoms except that the attending physician found considerable pus and a few red blood cells in the urine. Blood culture and a Widal test were negative. A leucocyte count was 16,000. There was some tenderness elicited over the right kidney. Cystoscopic examination under general anesthesia showed a typical colon bacillus cystitis which was principally confined about the right ureteral orifice. Both ureters were catheterized and cultures made from each sample. The right kidney urine showed a positive growth of pure colon. Autogenous vaccine was immediately made and administered within forty-eight hours, using somewhat smaller doses gradually working up to one c.c. The child was given eight injections by Dr. Butler and a remarkable recovery followed. In a letter from the child's mother, July 13, 1923, she stated that the child was perfectly well in every way.

Case IV.—Female, aged fifty, married, referred June 12, 1923, by Dr. Wilkin, of Rushville, N. Y., with a complaint of frequency and urgency of micturition, loss of weight and general weakness. The patient's trouble had begun about last December when she noticed that she had to get up about three times at night to void. She had lost fourteen pounds from December up to the present time and appeared rather weak. She had also had several chills. The patient had had tuberculous glands removed from the neck a few years ago, and with an additional family history of tuberculosis, every effort was made to rule out a tuberculous lesion. There was none found. A catheterized sample of urine showed it to be filled with pus cells and a few blood cells and a pure culture of colon bacillus was obtained. The cystoscopic examination showed a severe cystitis principally in the trigone. Culture from the right and left catheterized samples showed the same infection in both kidneys. An autogenous vaccine was made, and administered by her family physician, using the method outlined, and the patient has completely recovered from her symptoms. On July 13th the patient called at the office and a sample of urine showed negative findings. The patient is gaining in weight and strength. The only additional treatment in this case was the removal of several abscessed teeth.

CONCLUSIONS

1. Infections of the urinary tract due to colon bacillus can be completely cured by autogenous vaccines.
2. Larger dosages are recommended.
3. The interval between injections should not exceed five to six days.

Treatment of Scarlet Fever by Eucalyptus Oil and Carbolic Oil Versus Isolation.—G. Gushue-Taylor (*Lancet,* September 8, 1923) shows that the use of eucalyptus oil applied to the skin, and of carbolic oil to the throat in the treatment of scarlet fever does not prevent the occurrence of return cases, does not prevent the infection from spreading to susceptible patients and attendants during the course of treatment, and does not prevent secondary complications. The number of return cases varies inversely as the length of the period of detention, when this period is up to about eight weeks. In all cases of scarlet fever the patients should be isolated for at least eight weeks. They should not be allowed to mingle with other children until the ear, nose, and throat appear healthy.

Treatment of Hay Fever, Asthma, and Other Manifestations of Allergy.—W. W. Duke (*American Journal of the Medical Sciences,* November, 1923) says that the numerous manifestations of allergy, such as hay fever, asthma, dermatoses, gastrointestinal, urological, and neurological symptoms, urticaria, angioneurotic edema, and hypotension, can be treated along five lines, namely, avoidance or removal of the specific cause, avoidance or removal of contributory causes, specific protein treatment, nonspecific protein treatment, and symptomatic treatment. The first is to be preferred when possible. Specific protein treatment is best when the specific cause is known. When the specific cause is not known or cannot be removed or treated specifically, nonspecific protein treatment is worthy of trial. Adrenalin, pituitrin, and atropine are useful symptomatic remedies, well adapted for emergency and temporary use. Good results are obtained in hay fever and asthma through the subcutaneous use of pollen extract combined with local applications of pollen extract to the conjunctivæ and nasal mucous membrane.

Historical Medicine

Medicine and Philosophy in Virgil

JONATHAN WRIGHT, M. D.
Pleasantville, N. Y.

If one were to make an examination of the libraries belonging to those who have loved classical literature it is probable the most defaced and dog eared book in the majority of them would be found to be a Virgil. Among those who had long since passed the climacteric of life it might be a Horace. He would often hunt his friend close for second place. There are no such libraries now of course even put up at auction to close an estate, but notwithstanding the decay of the culture which found its joy in such bibliomanias, the modern historian of thought, if for nothing else, can hardly fail to find an interest in Virgil. He can hardly escape the curiosity to know just why Virgil sank so deep into the minds of men long after the glory of Augustus and the kindness of Maecenas had sunk with them into the tomb. For a while doubtless it was the marvel of his verse that endeared him to the men of the golden age, but that quickly passed into the silver age and that as quickly into the one merely of brass and junk. Yet Virgil's verse lived on, beyond Seneca's time even, a little obscured it is true by the fog and dust of a crumbling civilization, but nevertheless the model of the schools. As to this who can wonder who has learned to love the measured beat of his lines, but there was more to Virgil than this, more even than the splendor of his art in its higher functions. In the mire of the Middle Ages he lived still, clear up to the Renaissance, when he came into his own again by the magic of his art. It takes a high culture to feel the warmth the rays of such a luminary emits and even Comparetti (1) has not succeeded in making it clear to us why he was a necromancer and a wizard of knowledge, a scientist who knew the causes of things hidden from the best of the brethren of cloister and cell, even from those who knew how to write, who were the propagandists of the faith of a new civilization yet to arise. They could not have culled much magic, medical least of all, from the scrolls, but nevertheless there is in his works ample trace of a knowledge of the primitive life which existed long before the glory of Greece and the glow of its reflection in the Rome of Virgil's day. This may have had a sympathetic affiliation with a world again in ruins.

The modern ethnologist will here and there recognize primitive magic in a setting strange to him, one whose magnificence possibly the culture he himself has attained will not suffice for him to recognize, but the records of the primitive age of every civilization we know of, so far as its fundamental principles are concerned, may be discovered there, serving as the materials of Virgil's art, for those records infinitely varying in detail are essentially the same wherever we meet them and they cluster around a pantheism which lies at the root of much of our own metaphysical beliefs. Possibly even these are so worn threadbare in the thought of the modern reader that he will toss the book from him, but if the ancient monk had no more appreciation for Virgil's art than the modern scientist, and who could have less? if the music of the lines made no appeal to him, nor the nobility of the images they evoke, the old mumbler of paternosters may have chanted them to himself as invocations to a saint who had value in the Christian's hierarchy. Those in which are recorded the sacrificial rites Æneas uses to honor the manes of his father hark back to a past in which both archeologist and ethnologist meet.

> ". . . magna medius comitante caterva
> hic duo rite mero libans carchesia Baccho
> fundit humi, duo lacte novo, duo sanguine sacro,
> purpureosque jacit flores ac talia fatur:
> 'salve, sancte parens,' iterum salvete . . ." (2)

Barring the purple flowers, of the poet's touch, the wine and the milk and the blood, two bowls full of each, poured to Bacchus and the other deities and the chant to the sainted father would have its appeal to the mediaeval monk as well as to the African savage medicine man, *"medius comitante caterva,"* the central figure with the whole world following and looking on. Was this too not something for those who led the processions to the shrines in the middle ages to think upon?

The modern scientist sees the blood sacrifice and his mind travels back, if he is an archeologist or historian, along that ghastly trail and beyond to human sacrifice. It lingers with the multitudinous observances of many modern tribes with which it may still be seen to be woven. But there is more still in Virgil than that, for as the monk reads, as the scientist reads, if he has been brought up as he should, which he isn't today, the cadence of the lines, the measured alliteration, the images of beauty that fill his mind's eye drive him along to other worlds. As for the classicist he never gives the magic, the unmistakable track of the cave man, a thought. He swims along oblivious to all the traces of primitive magic, but we can not afford here to let Virgil's enchantment, his real bid for the wizard's wand, beguile us to that extent or we will lose many a hint as to the folk medicine of Virgil's day.

Among the first lines (1.50) in the first Eclogue we find the shepherd cautioned he must see to it not alone that no strange food lies in the way of his fat young flock but he must beware of the contagion of some neighboring herd:

> "nec mala vicini pecoris contagia laedent."

Upon this line I have dwelt before, comparing it with certain expressions of Varro, Columnella and Seneca, which warrant, so the original collators of them venture to suggest, the very strong inference that the conception of minute animalcules as the etiological factors in disease was in existence. An attentive study of the materials for a history of thought will reveal numerous demands for theories and discoveries which were more exactly formulated

or actually achieved only after ages, during which instances such as this from time to time are visible on the surface in the records remaining to us. Lucretius (16) seems to accept the view I have alluded to, though I am not sure the passage is entirely free from ambiguity; "Many living things in the food which bring disease and hasten death, atoms so small their contact can not be avoided which pass into the nose and air tubes." There is further on in the same book reference to pollution of the air by living matter causing infection among men. The necessity the human intellect had for the minute divisibility of matter brought into being the abortive atomic theory of Leucippus and Democritus, with which antiquity worked as best it could until Dalton, a century or so ago, placed it upon a higher plane of usefulness. This is quite aside from the accuracy with which it in the final analysis presents its scheme of nature. It is a pragmatic demand the mind makes confronted by a mass of nonabsorbable material. It does not demand a true theory, but one that works, and that demand, slumbering perhaps for a thousand years, lights up again and again, if the facts on which it is based continue to obtrude themselves at intervals, until some arrangement can be made which relieves the mind for a time of their intrusion. Necessarily the vast majority of facts in existence at any one time, rapidly become mere junk. They may be the truth, snow white and impeccable, but unless they fit in with some orderly and compact package of theory so the mind can pack them away in the smallest possible cranny of consciousness, they perish, perhaps to undergo metempsychosis and appear again, but for all practical purposes they are dead. Go into the stack rooms of the libraries and you will see their coffins mouldering on the shelves for a lack of demand, millions of them.

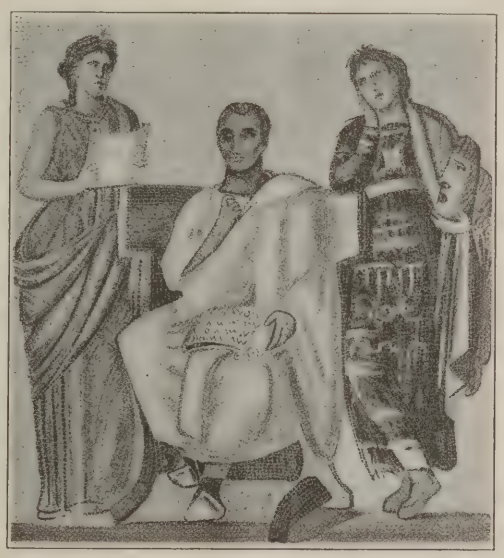

FIG. 1.—Reproduction of a mosaic found at Susa, in Tunis, the Adrumetum of Roman Africa. Virgil is seated between two Muses. One is reading a scroll, the other, clad in a comedienne's robe, is holding in her hand a stage mask. The poet has on his knees a manuscript on which one can make out a verse of the Æneid (1.8.): *Musa mihi causas memora quo numine laeso.*

The verdict for the contagiousness of phthisis was demanded by circumstantial evidence many generations before Koch discovered his germ. The germ itself of the idea existed in men's minds, before the time of Virgil, as we have seen, and long after him Bruno had it, three hundred years before Pasteur; others too, I know not how many, but some of them getting the conception from Lucretius and the ancients, no doubt. We can hardly imagine a time when the facts of contagious disease did not press for solution, whether among the swarms of men or in the herds of sheep that graze in Virgil's pastures. They were always knocking at the door of the mind for admission. More than two hundred years elapsed after you could see the animalcules which filled the minds of the ancients on whom Virgil leaned, before it occurred to some one, no one knows exactly who even now, to build a theory that worked for a generation and has now become one of the processes of disease, despite the blunders of Koch's postulates, and we are looking in other directions for the "cause."

"Felix qui potuit rerum cognoscere causas," Virgil sighed, probably after having read Lucretius. We are only successful when the "causes" become processes. Virgil would not have been happy, for the "cause" constantly recedes, but was he not aware of that or was he only as silly as the men of science who sigh at the thought the "causes" of disease have now become known for the first time, in their generation and by their Herculean labors?

It is, however, profitable, historically speaking at least, to look upon the progress of thought as the result of a law of supply and demand, but like many of the laws of nature it seems to work with an enormous waste both of materials and of energy, this machine of the gods which converts "causes" into processes.

Not until there arose out of the edifice founded by Pasteur and Lister and Koch a demand of the human intellect for some more efficient carrier of contagion than the air, a vehicle in use since Virgil's day, was the intermediary between the receding "cause" of disease, the germ, and the disease itself discovered; the mosquito, the louse, nay man himself. The carriers of disease, are they not "causes" too? Air with something wrong with the pneuma in it was once a cause of disease, and some of us still surviving are old enough to remember when sewer air was the cause of it and then the carrier of it, until the robust man who cleaned the sewers laughed us out of the notion, and that "cause" went grumbling down the aisles of time. In my visions of the past I still see a loved instructor of mine, a learned professor of the practise of medicine, berating, with swollen veins on his temples and a flush on his cheeks, an hotel clerk who was appalled at his indictment by the irate man of science. He had given him a room with a wash basin connected with the sewer in it. In the excited language of the endangered guest, this clerk must have sent hundreds thus to their doom. My irascible friend has long since paid the debt he owed to nature, but he did not die from sewer gas poisoning. It is not necessary to point out how much is true or how much false in the once exploited alarm about sewer gas. It was a theory that rapidly arose as house plumbing had come to be universal. It worked in so far at least that it stimulated care in sanitary precaution.

If bad air, either ancient or modern, was the passing phenomenon of misdirected etiological theories, if we have rejected it as the carrier of infection, we are in ardent pursuit still of the carrier. We have

ceased to worry about or have much use for "causes" and perhaps the readjustment of ideas as to them is one of the chief, perhaps it will be a permanent, advance over ancient ways of thinking. When Virgil, who knew of the contagion in the scab of sheep and who probably came to know from Varro, or from the same sources as Varro and Columnella and Seneca afterwards did, of the theory of animalcules as the causes of disease, wrote the Culex he was but a boy. It was the gnat or the buzzing mosquito, which after two thousand years was to be dragged forth from his obscurity into the sequence of the phenomena of disease in man, and which was no doubt in his day as in ours carrying infections over the Campagna, but he fits the mosquito into the pantheism of his time and makes it an instrument in the hands of God.

In a very remarkable production for a boy of sixteen or seventeen he weaves this philosophy with much elaboration of other beliefs into a very pretty little tale, speaking in his favorite rôle of shepherd. He tells how its buzzing annoyed him and how its sting awakened him from his sleep on the grassy banks of some stream, and saved his life from the venom of a snake stealing upon him, but a blow of his hand had killed his benefactor before he knew of his danger. The sinister importance into which the mosquito has swelled for us tends to make perfectly absurd the pathos which fills the concluding lines of the poem recording the gratitude of the shepherd who performs the funeral obsequies:

> "parve culex, pecudum custos tibi tale merenti
> funeris officium vitæ pro munere reddit." (11)

If we shall find Virgil alive to the mystic influences of the pneuma in the physiology of living creatures we can see only here and there that this thought with him extends also to morbid conditions. For him as for my friend it was an air borne infection. Rather better than in the bucolics it is seen in the Æneid (4). Æneas tells Dido of his experiences in Crete. When he was busy there regulating the affairs of the inhabitants, "suddenly a plague of sickness and a death laden season fell upon their bodies and upon the cultivated fruit trees as well, a pitiful time due to the state of the atmosphere they inhaled." We might think this a reference to bad weather conditions in common parlance just as we shall see as to the supposed cause of the "scab" in sheep, but it is not, it is in the Hippocratic sense. The idea of air borne disease of this kind rested on essentially a mystic conception, that of some derangement in the pneuma in the atmosphere and it is this we must read into the *"corrupto caeli tractu."*

This is brought to our mind by what Æneas learns later from his father Anchises in Hades. This divine affluence animates all creation. "There is a fiery force of celestial origin in the seeds of living things so far as their bodies are not clogged with noxious principles and their earthly forms and mortal limbs do not languish" (5). These ills of the flesh have an ethereal origin for the soul does not at once shed them when it flees beneath the earth to Hades. There, like their sins, they have to be expiated, worn away by various purgations and purifications, before the soul is free of them. We see here then corporeal sin and moral sin, disease of the soul and body closely allied. In both it is the impurity in the pneuma, in the divine affluence which must be purged away in Purgatory or Hades, its prototype.

(To be concluded)

Contributors to the Science of Medicine

SIR WILLIAM OSLER, Bart.

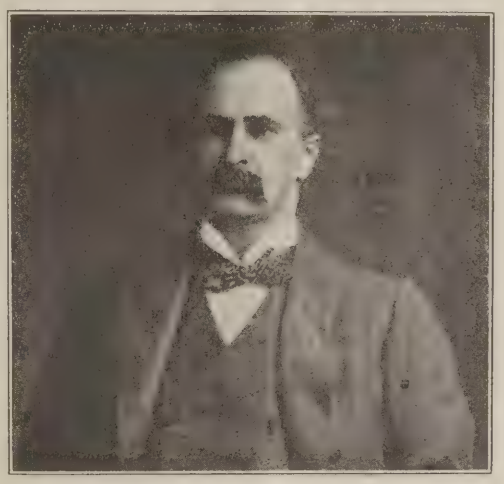
Once when Sir William Osler was asked to make an address at a service for the students of the University of Edinburgh, he chose as his subject Man's Redemption of Man, and as his text the following passage from Isaiah: "And a man shall be as a hiding place from the wind, and a covert from the tempest; as rivers of water in a dry place; as the shadow of a great rock in a weary land." Perhaps no passage in all literature is as fitting as this one, which he himself all unconsciously chose, to describe what this great man meant to those who knew him.

William Osler was the eighth of nine children. He was born in 1849 at Bond Head, Ontario. His father, Featherstone Osler, with his wife had left Falmouth in 1837 and come to Ontario to settle. William was graduated from Trinity College, Toronto, in 1868 and received his medical degree four years later from McGill University, Montreal. Following his graduation he spent two years in study abroad, returning in 1874 to Montreal, where he became professor of the Institutes of Medicine at McGill. Thus at the age of twenty-five he filled a chair covering both pathology and physiology, a position which he held for ten years. In 1884 he accepted a post in the University of Pennsylvania, and five years later was called to Baltimore as professor of medicine in the then newly established Johns Hopkins Medical School. In 1892 he was married to Grace Revere, a descendant of Paul Revere. He remained at Johns Hopkins for sixteen years. In speaking of this period of his career, Harvey Cushing writes: "It was the Golden Age of Johns Hopkins during the presidency of Daniel C. Gilman, and during this period through his writing and teaching Osler became recognized, one may say without exaggeration, as the most eminent and widely influential physician of his time." In 1904, when he was fifty-six years of age, he accepted the Regius professorship of physiology at Oxford, which was the most honorable post that the United Kingdom could offer. Throughout his whole life at Oxford, he and Lady Osler kept open house, especially for Canadian and American students, and

were so cordial and hospitable that their home won the name of "Open Arms." They entertained successive groups of students weekly and it was said that Osler never forgot a name.

Osler was a fellow of Christ Church, Woolsey's College; a member of the Hebdomadal Council, a curator of the Bodleian Library, a delegate of the University Press, a member of the Samuel Pepys Club, of the Roxburghe, the Colophon, the inner circle of the Royal Society, and the Johnson Club. At one time he held the office of president of the Classical Association.

He traveled a great deal, usually accompanied by some students, and his notes, letters and even postcards, written to acquaintances and friends, contain some of the most charming, interesting and witty specimens of his writings. Cushing characterizes him as a writer *par excellence* of countless brief missives, containing some characteristic message, quip or epigram worth preserving. Of his scientific writings, the best known is his *Principles and Practice of Medicine,* which has gone through nine editions, and still remains probably the most used and most useful book in medicine today. It has been translated into French, German, Spanish, and Chinese. The bibliography of his works contains more than 730 titles. Among these are some of the earliest discussions on the blood platelets; descriptions of the visceral complications of erythema multiforme, multiple telangiectasis, and chronic cyanosis with polycythemia and enlarged spleen; special monographs on the cerebral palsies of children, chorea, abdominal tumors, angina pectoris, and cancer of the stomach; his description of the erythematous swellings (Osler's spots) in malignant endocarditis is well known. Among his contributions to historical medicine are his essays on Linacre, an Alabama Student, and Servetus. He was editor of *Modern Medicine.* His clinics at Johns Hopkins were noteworthy for students of malarial fever by Thayer, of amebic dysentery by Councilman and Lafleur, the finding of the microorganisms in gonorrheal endocarditis and septicemia by Thayer and Blumer, the studies of eosinophilia in trichinosis by Thayer and Brown, the demonstration of sexual conjugation in malarial parasites by MacCallum and Opie, and the study of pneumothorax by Emerson.



SIR WILLIAM OSLER

Unfortunately the best known incident of Osler's life, at least to the layman, was that connected with the quotation about "chloroforming all over sixty." This remark, quoted in a spirit of jest from one of Antony Trollope's less known novels, *The Fixed Period,* was made in the course of his farewell address to his friends and colleagues in Baltimore, many of whom were over sixty, an age which he himself was approaching. Most unhappily the press heartlessly singled out and featured as good copy the one remark about chloroform. The notoriety of this incident, coming as it did upon the eve of departure from America, was most painful to Osler, but he wisely refrained from making any reply.

His Ingersoll Lecture on Science and Immortality is typical of his intellectual keenness, as well as of his charm of style. The story is told that he could not find time for the preparation of this lecture until a few days before it was due. In desperation, he slipped away one night to New York, and there in the University Club wrote the lecture in a single morning. In it he makes his own confession of faith —that he would rather be mistaken with Plato than be right with those who deny life after death.

His death at the age of seventy was probably a consequence of the war. Although no man ever hated strife and conflict so much, nevertheless he made himself enter energetically into many war activities—committees, hospital work, and as senior consultant to the forces, for which duties he received a colonel's commission. Many believe him to have been the writer of the British reply to the well known German professional note issued early in the war. His only son, Revere, who was also a hater of strife, underwent training as a field artillery officer, was commissioned lieutenant, and, after serving bravely in France for a year, was mortally wounded at Ypres, and lies buried in Flanders Field. His father never recovered from his boy's death. Though outwardly unchanged, he suffered greatly from insomnia and his health became undermined so that he succumbed to the return of an old ailment, bronchial trouble, which developed into pneumonia, one of the complications of which made an operation necessary, from the effects of which he died on December 29, 1919. One of the best and most interesting biographical sources on Osler is the July, 1919, number of the *Johns Hopkins Bulletin,* composed of contributions by a number of his former pupils and colleagues in Baltimore. This was published to celebrate Osler's seventieth birthday and came as a great surprise to him, who was averse to all public testimonials and adulation.
